Appraisals of community complexity may also be made using the pattern of biotic interactions that links species in a community. The notion that biotic interactions are the primary elements of structural intricacy (complexity) that determine community dynamics has been the dominant theme in community ecology for several decades, inspired by the original contributions of Lotka and Volterra. Mathematical treatments of complexity have explored the consequences of varying interactions by constructing model communities whose species richness, interaction coefficients, and signs and strengths of interaction vary randomly and by examining their stability features. The heart of this approach is to use the “community matrix” as a measure of complexity, a concept formalized by Richard Levins in 1968 and still very much in use today. The general approach is to assume that all populations can be modeled by differential equations of the form

$$\frac{dx_i}{dt} = r_i x_i \left(K_i - x_i - \sum \alpha_{ij} x_j \right) / K_i$$

where r_i is the intrinsic rate of increase of the population of the i th species, K_i is the carrying capacity of the i th species, x_i is the population size of the i th species, and α_{ij} is the effect of the j th species on the i th species. For a community at equilibrium, where

$$K_i = x_i + \sum \alpha_{ij} x_j$$

the system of equations can be written as

$$AK \equiv K$$

Here, x is the column vector of species population sizes, K is the column vector of species-specific carrying capacities, and A is the community matrix

$$A = \begin{bmatrix} 1 & \alpha_{12} & \alpha_{13} & \cdot & \cdot \\ \alpha_{21} & 1 & \alpha_{23} & \cdot & \cdot \\ \alpha_{31} & \alpha_{32} & 1 & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & 1 \end{bmatrix} \quad [3]$$

The properties of this matrix can then be used in analyses of complexity. Although wonderfully appealing as a logical measure of community complexity, identifying and quantifying interactions in a community is a formidable task and requires that a community be at or near equilibrium, rarely the case in nature.

One concern over measures of structural complexity based on biotic interactions is that they must account for “keystone” species. Defined originally by Paine (1966) as a predator species that fosters the coexistence of competing prey species and thereby promotes structural complexity in ecosystems, it has become colloquially used to describe any species that has a disproportionate impact on the community in comparison to other resident species (Liebold, 1996) or species that serve as ecological engineers (Jones *et al.*, 1994).

Power *et al.* (1996) proposed that the distribution of “community importance values” (CIVs) may serve as a tool for comparing communities for this element of structural complexity. Formally, the i th species in a community has a community importance value (V) defined as

$$V_i = [(m_N - m_D)/m_N](1/p_i) \quad [4]$$

where $m_N \equiv$ the quantitative property (e.g., production or rate of decomposition) of the intact community, $m_D \equiv$ the quantitative property of the community with the i th species removed, and p_i represents the proportional abundance of the i th species before it was removed. In practice, one would sequentially delete one species at a time, each time measuring the community response to such a loss. Eventually a distribution of CIVs would be obtained and statistics (e.g., the mean or modal CIV and its variance) could be used to compare one community with another.

Communities with mean CIVs furthest away from 0 would be more complex than those whose distributions were not significantly different from a normal distribution with a mean of 0. Of course, such an experiment would be very difficult to conduct and Power *et al.* (1996) could identify only two such studies.

One approach to the intractability of contending with all species interactions is to focus on a subset of interactions. An example of such a focus is the study of feeding or trophic interactions. Typically, food-web statistics serve to quantify food-web structural complexity. These statistics include food chain length, connectance (the ratio of existing trophic links to possible links), compartmentation (the number of compartments or isolated subnetworks of interacting species in a food web), the ratio of predator species to prey species, and interval versus noninterval state (presence or absence of complex overlaps in resource sharing). The difficulty with all of these statistics is that they rest entirely on the quality of the set of food webs, many of which were not constructed for such analyses, and thus produce artifacts when subjected to such analyses.

Measures of Functional Complexity

From a functional perspective, complexity has been measured simply as the number of functional groups, but this approach is steadily being abandoned in favor of measures based on

species' traits. Functional groups are collections of species that are related by their ecosystem activities, though many other definitions have been used. For example, if a functional group were defined as the group of species sequestering carbon from the atmosphere by photosynthesis, then all macrophytes, algae, and cyanobacteria found in a lake would be considered part of this group, in spite of their very different ecologies and evolutionary histories. This degree of aggregation is much larger than what is typically found in contemporary food webs (trophic groups or species), community matrices (interaction coefficients from species pairs), or high-resolution phylogenies (orders, families, genera, species, etc.). Species' traits are the phenotypes, characteristics, or properties of species that determine how a species responds to or influences their environment. For example, the average metabolic rate of individuals of a single species of mammal for a given set of conditions tells us how that species responds to its environment whereas the amount of carbon dioxide released by that species tells us its influence on the environment (i.e., carbon cycling).

In the same way that tallying up numbers of species fails to capture complexity, tallying up functional groups is unlikely to serve as an adequate measure of functional complexity. More important would be the degree of parallel versus serial dependency among species in an ecosystem. As in community complexity, network architecture is the focus for measuring complexity, but rather than linkages of biotic interactions, only linkages of dependencies among species and functional groups become important.

Ecosystem reliability is an example of an index that combines measures of serial and parallel dependency (Naem, 1998). Serial dependency occurs when every species or every functional group is dependent on the other for the ecosystem to function (e.g., decomposers depend on producers for energy whereas producers depend on decomposers for nutrient cycling). Parallel dependency occurs when one or more species within a functional group substitute for each other on the extinction of one of the members of the group. In its simplest form, ecosystem reliability may be formally represented as

$$H(t) = \prod_{j=1}^F \left[1 - \prod_{i=1}^{S_j} (1 - e^{-\lambda t}) \right] \quad [5]$$

where F is the number of functional groups, S_j is the number of species in the j th functional group, and λ is the probability of extinction over a small increment in time, t . Note that the reliability of an ecosystem is defined as 1 ($H(0) \equiv 1$) and eventually decays in the absence of replacement of species by recolonization ($H(\infty) \equiv 0$).

As in other measures of complexity, the information needed for this index is difficult to obtain. Species presence or absence, local extinction rates, and functional roles are often difficult to determine without considerable empirical work. Focusing on redundancy demonstrates, however, that if the properties being measured are the result of the collected activities of groups of similar (i.e., redundant) species, such as production, having many species could actually mean more steady levels of production (less complex behavior). Thus, the association between biodiversity and complexity of ecosystem

functioning is dependent on the degree of species redundancy in the system.

Because functional groups are sometimes seen as arbitrary (Wright *et al.*, 2006), metrics based on species' traits have multiplied dramatically since Petchey and Gaston (2002) introduced the first index that became widely used in ecology. In Schluter *et al.*'s (2010) review of metrics of functional diversity they identified three classes of functional diversity metrics; measures of functional richness, divergence, and evenness. If one considers each trait of a species to be a different axis (e.g., metabolic rate, body mass, and temperature where a species is found), then each species occupies a specific volume in the space described by these trait axes. Three axes describe a three dimensional space, or trait space, which is easy to visualize, but the space can, of course, range from unidimensional to hyperdimensional depending on how many traits the researcher decides are important in their study. Functional richness concerns how much of that space is occupied by all the species in an ecosystem. Functional evenness concerns how uniformly the trait space is filled by species whereas divergence concerns how distant species are from one another in trait space.

Measures of functional diversity, because they are based on traits, their means, their variances, and their correlations with one another, are much more difficult to estimate than other measures of biodiversity, such as H , which are often based solely on the relative abundance of species. For illustration, we can consider Schleuter *et al.*'s measure of multidimensional functional richness (FR_{Im}) as an example of how one might quantify functional diversity. One version of this measure is

$$FR_{Im} = \int \max_{s \in S_c} \left[\exp \left(-0.5 (\mathbf{Z} - \mathbf{X}_s)^T \sum_s^{-1} (\mathbf{Z} - \mathbf{X}_s) \right) \right] d\mathbf{Z} \quad [6]$$

where s is the s th species, c is the c th community, S_c is the number of species in the c th community, T is the number of traits, $\mathbf{Z}$ is the vector of trait values, $\mathbf{X}_s$ is the vector of trait means for the s th species, $\max_{s \in S_c}$ is the maximum value of the bracketed function for each species in the set of species in the c th community, and $\sum_s^{-1}$ is the variance/covariance matrix of traits. Essentially, this metric estimates the space occupied in a trait space of T dimensions (one dimension for each trait used) by integrating over the distribution of maxima of every species occupancy (based on their means and variances for each trait) while correcting for covariation among traits (e.g., if two traits correlate perfectly then they should influence the metric as if they were one trait). This is neither easy to comprehend or calculate, though in principle the data needed are relatively straightforward to collect. Measures of functional evenness and functional divergence are equally complex.

It is important to note that although measures of functional diversity based on traits obviate the arbitrariness of assigning species to groups, which traits to use can wind up being another source of arbitrariness. In principle, one does not use any and all traits available or some arbitrary set, but uses the set of traits relevant to the ecosystem function of interest. Determining which traits are relevant requires

modeling an ecosystem process or property as a function of species' traits.

Measures of Phylogenetic Complexity

Although community and functional complexity focus on structural aspects of ecosystems, phylogenetic complexity examines the structure of the phylogenies that relate species to one another within a community by their evolutionary history. As with community and functional complexity, the number of species is an important starting point, but the architecture of the evolutionary "tree" or "bush," as opposed to network architecture, serves as the primary basis for assessing phylogenetic complexity.

A straightforward measure of phylogenetic complexity might be simply the sum of the lengths in the tree that unites all species in the set being examined or a simple modification of the Shannon–Weaver index in which species are weighted by their taxonomic distinctness. More informative, however, is the "phylogenetic moment" (defined in eqn [6]), which provides a statistic by which communities might be compared. A difficult necessity for using this measure is that one has to have the complete phylogenetic tree at hand (referred to as tree T), including those species that might have gone extinct and might be missing from the local community being examined. The current community will consist of some subset of T (referred to as set R), and the local community that one is measuring will invariably be missing some species and contain an even smaller set of species (referred to as set r). If we assume that the tree (its nodes and branches) can be represented by a series of points in time, with a total of PT points for the whole tree, then the phylogenetic moment for this subtree (M_R) is

$$M_R = \sum_{p \in P_r} d_{pr_p} \quad [7]$$

where d_{pr_p} is the distance between a point on the tree and the nearest species in the set r . The smaller the phylogenetic moment is, the more closely the community represents the full phylogenetic structure (found in T). For example, in Figure 3, although the total distances among the species in trees R_1 and R_2 are the same, using the phylogenetic tree T , which includes extinct species F and G and missing but extant species B , shows that R_1 would have a smaller phylogenetic moment than R_2 because C would have more near neighbors than D . That is, A , C , and E will presumably contain genetic information more representative of the bulk of the species in the full tree (T) than A , D , and E .

Metrics of phylogenetic diversity can also include the relative abundance of species (Cadotte *et al.*, 2010) which can make them more comparable to indices such as the H , C , V_i , or FD_{Im} .

Utility of Measures of Ecological Complexity

Although several measures of complexity or proxies for complexity based on measures of diversity have been developed and explored ((1) through (7)), in reality no single measure is likely to adequately describe ecological complexity in all its

Figure 3 Hypothetical phylogenetic trees. Tree *T* represents the tree for all taxa in the community, including extinct species *F* and *G*. Two current local communities, each missing species *B* and one other extant species (dashed lines), are illustrated as *R*₁ and *R*₂. Solid lines show trees that would be used in calculating the total phylogenetic distance among species. Note that they are the same for *R*₁ and *R*₂. The phylogenetic moments for these trees would be the sum of the distances from each point on the tree *T* to the nearest species present. The moment would be smaller for *R*₁.

forms. Virtually any index based on a subset of the factors listed in [Table 1](#) is likely to produce rankings in complexity that will not agree with other methods, much in the same way that different diversity indexes may disagree in how they rank communities. The quantification of complexity is hindered by the difficulty in uncovering all species and all their interactions, their functional roles, and their phylogenetic relationships. As the next section shows, this means that we currently have only a partial picture of how complexity and biodiversity are related.

The Significance of Ecological Complexity

Complexity in Nature

Although diversity and complexity are practically universal features of ecosystems, we have much better information on diversity than on complexity. The estimation of existing

diversity is, to be sure, challenging, but determining the distribution and abundance of species would only be the starting point for investigations of ecological complexity.

Unfortunately, the components of complexity are extraordinarily difficult to measure and for this reason empirical treatments have lagged behind the substantially greater progress made in theoretical explorations of the significance of ecological complexity. An ecologist never has a complete inventory of all species within a region, let alone their relative abundance, biotic interactions (direct, indirect, and higher order), phylogenetic relationships (at the regional level, including extinct species), functional roles, functional traits, and population and process dynamics, or other details listed in [Table 1](#).

In most cases, however, the question to hand is more focused and thus more tractable. If the question concerns population stability, then quantifying only community complexity may suffice. If the question concerns what sets of species are most likely to contain the bulk of genetic information stored within a regional biota, then quantifying phylogenetic complexity may be enough. If the question concerns the magnitude or rate of ecosystem functioning, then quantifying functional complexity may do.

Community Complexity

An early and influential work that examined community complexity was [MacArthur's \(1955\)](#) study, inspired by Odum's theory that the "amount of choice which the energy has in following the paths up through the food web is a measure of the stability of the community." Using the Shannon-Weaver formula to model the number of alternative pathways and relate this to stability, MacArthur concluded that "stability increases as the number of links increases," though he was primarily considering resistance stability (remaining intact in spite of perturbation).

The theoretical relationship between complexity and stability is treated elsewhere in this volume, but it is worth noting here that this theory stimulated further investigations into the relationship between complexity and ecological processes, such as population dynamics. Later mathematical studies of local resilience stability (the ability to recover after perturbation) showed an inverse relationship between community complexity and resilience stability. Studies of connectivity and connectance (the nature and degree of connections among species) showed that resilience stability could either increase or decrease, depending on which trophic level was examined and the degree of connectance. [Pimm \(1979\)](#) also showed that complexity and stability could be positively related if one considered the deletion of species rather than resilience stability. Thus, those biologists who observed a positive association and those who observed a negative association between diversity and complexity more than likely differed in how they defined stability or how they defined complexity. Suffice it to say that there was agreement that complexity and stability were indeed related, but the nature of the relationship was dependent on one's definitions.

Although food-web studies initially showed much promise as a means for examining the relationship between complexity (community structure) and diversity by focusing solely on trophic interactions, early findings did not fare well in the test

of time. Polis and Winemiller (1996) summarize four patterns derived from early analyses of topographic or static food webs. First, there is constancy in the number of links per species in a food web irrespective of number of species. Second, the numbers of trophic levels seem to be invariably small (three or four). Third, the ratio of predator to prey species is relatively constant. Fourth, omnivory is rare. All of these patterns, however, have been challenged as artifacts.

Though potentially artifacts, food-web patterns at least touched on an obvious truth about communities – there are likely to be constraints in the structures of food webs. For example, at the simplest level, one cannot have consumers without resource species (i.e., no predators without prey) and there are likely to be stability or energy constraints that limit food chain lengths (Kaunzinger and Morin, 1998). Currently, food-web biology has gone far beyond the sorts of patterns that initially stimulated research in this field, but new patterns, if they exist, await the completion of a new set of higher resolution food webs.

The main observation to be drawn from studies of community complexity is that complexity is never at its maximum in diverse ecosystems. For example, although the potential number of pairwise interactions is large for any community, few of these interactions may ever be realized. As Margalef (1985) states, “the considerations of artifacts (from mathematical studies of diversity and complexity) provide an elementary but effective approach to the assertion that no system is completely interlocked or connected.” We may infer from this fact that complexity asymptotes with diversity, an important consideration in our quest to understand the relationship between diversity and complexity (see Figure 2).

Phylogenetic Complexity

The relationship between phylogenetic complexity and biotic diversity is not well understood. Globally, estimates of origination and extinction of species suggest more or less steady increases in biotic diversity punctuated by aperiodic mass extinctions (Kirchner, 2002). This steady rise may be taken to mean that origination rates, more than millions of years, have been outpacing extinction, except during periods of mass extinction, and that recovery from mass extinctions has always occurred. Such a history of the biota suggests to some that the biota can tolerate even very deep “prunings” of the tree of life. At a global level, this suggests that random sets of species drawn from regional pools are likely to contain equivalent amounts of genetic information and that it takes severe levels of extinction to reach the point where insufficient genetic information is left in the remaining taxa to regenerate lost biodiversity. Because large-scale patterns in diversity across environmental gradients are similar across many taxa (Currie, 1991), we may expect that random samples from communities would result in phylogenies of similar complexity. Of course, since only a fraction of all species have been described, it is difficult to know exactly what the distribution and abundance of species are. As in community complexity and functional diversity, the true relationship between diversity and complexity is unknown, but it is likely to be asymptotic. That is, highly diverse systems may experience little change in phylogenetic complexity in the face of moderate levels of extinction.

Ecosystem Functioning

Biodiversity and ecosystem functioning are treated elsewhere in this Encyclopedia, but here the author examines its relationship to complexity and functioning. May (1974) noted in his “afterthoughts” to the second edition of his influential book that aggregate properties of communities, such as production (i.e., ecosystem functions), could show the opposite relationship with complexity that dynamic stability showed. Theoretical support comes from different approaches, but experimental tests of the idea are few. Support for this idea can be found in Tilman and Downing’s (1994) study of experimental grassland plots. In their study, production recovery from a drought (resilience stability) increased with plant diversity. Two laboratory microcosm experiments using freshwater microbial communities by McGrady-Steed *et al.* (1997) and Naeem and Li (1997) showed that predictability and reliability of ecosystem functions, such as production and community respiration, can indeed be associated with biological diversity and complexity. The study of biodiversity and ecosystem functioning began in the 1990s and the number of studies has grown exponentially since then, but how complexity affects ecosystem functioning remains dominated by theoretical rather than empirical studies (Griffin *et al.*, 2009; Loreau *et al.*, 2002).

The shift away from taxonomic diversity to functional and phylogenetic diversity, which better relate to ecological complexity, has been on the rise in biodiversity and ecosystem functioning research (Cadotte *et al.*, 2008). Understanding the distinctions between functional, phylogenetic, and taxonomic diversity (Swenson, 2011) offers much promise for advancing our understanding of how ecological complexity influences ecosystem functioning.

Conclusions: The Disentangled Bank

Common usage of the term “complexity” in ecology implies that ecological complexity is a function of the phylogenetic, functional, and community structure of ecosystems in relation to temporal and spatial patterns in the distribution and abundance of species. Most natural processes, such as origination, local and global extinction, biogeography, demography, dispersal, biotic interactions, niche relationships, and energy and nutrient flows, to name but a few, contribute to overall complexity, which makes it difficult to define precisely or quantitatively. Biodiversity, which is a function of the spatial and temporal extent of genetic, phylogenetic, taxonomic, and functional diversity, is similarly difficult to treat with precision. These two constructs in environmental science are very real and perhaps best defined in the way the United States Supreme Court Justice Potter Stewart famously defined pornography; “... I know it when I see it.” Some ecosystems are clearly more complex and some more diverse than others even if we have difficulty being precise about what it is we mean.

On the surface, ecological complexity and diversity seem so closely related that it is tempting to consider “biodiversity” as synonymous with “complexity.” If we consider complexity to be the structural and process intricacies of a system, however, it is clear that diversity, in terms of numbers and types of organisms in a community, shows no necessary relationship

with any measure of complexity aside from the trivial fact that without any diversity there is no complexity. Thus, two communities identical in numbers of species could be quite different in community, phylogenetic, or functional complexity, as illustrated in [Figure 1](#).

Studies of complexity in nature suggest asymptotic relationships between complexity and species richness, where species richness represents one way to define biotic diversity independent of complexity. It is hard to imagine, for example, that tropical rain forests, where species often number in the thousands, will show much reduction in complexity in the face of the loss of a few species. Current rates of extinction, however, are estimated to be staggeringly high and many diverse systems, such as tropical ecosystems, are not suffering extinction of species within their boundaries so much as they are being transformed to depauperate, managed ecosystems.

Thresholds in the response of ecosystems to the loss of diversity are particularly of interest ([Levin, 1997](#)) and these may be hypothesized from current knowledge about the relationship between diversity and complexity. Sometimes referred to as tipping points, critical transitions, regime shifts, or catastrophic change, the possibility of a rapid change in the dynamics, properties, or behavior of an ecosystem is of considerable concern in a rapidly changing world ([Scheffer et al., 2009](#)). Habitat modification such as conversion to agriculture, habitat degradation due to pollution or mining, over exploitation of biotic resources such as deforestation or overharvests that lead to collapsed fisheries, and ecological homogenization due to widespread transport of species among communities, to name but a few aspects of global change, all contribute to ecological simplification, or the loss of ecological complexity. From what is known about nature, both theoretically and empirically, it is reasonable to postulate that both community and phylogenetic complexity show asymptotic relationships with diversity. Because functional complexity aggregates many species into small numbers of functional groups (e.g., all plants may be considered producers), we can postulate that the asymptote for functional complexity will be lower than that for community or phylogenetic complexity. When these are plotted together, as shown in [Figure 4](#), we can identify two thresholds of interest. At some point (admittedly difficult to define precisely without accurate measures of community complexity or phylogenetic complexity), one will continue to experience no appreciable loss in functional complexity, but ecosystem properties, such as dynamic stability, may change and genetic resources will decline. As diversity declines even further, functionality is eventually lost after the second threshold (the leftmost dotted line in [Figure 4](#)) is crossed.

Managed ecosystems, such as aquaculture systems, farms, or monoculture tree plantations, most likely reside at the lower threshold, where the managers maintain the system at its minimal diversity. In general, these ecosystems may be functionally complete, containing all necessary functional groups to ensure that the desired ecosystem functions are maintained or, if not functionally complete, humans provide missing functions, such as fertilizer addition where nitrogen fixers have been removed. Complex systems are always more difficult to manage, but there are likely costs and

Figure 4 Hypothetical relationships between complexity and species richness. $C \equiv$ complexity. Vertical dotted lines indicate where the threshold in ecological consequences of declining ecological complexity might be identified. $C_c \equiv$ community complexity; $F_c \equiv$ functional complexity; $P_c \equiv$ phylogenetic complexity.

consequences for resorting to simple systems, many of which have to do with system stability, system utility, and system efficiency, as the material in this article reveals.

The appropriate metaphor for the process of human transformations of ecological systems may be the disentangled bank, or the converse of Darwin's entangled bank. As the earth's ecosystems are steadily transformed to agro-ecosystems and aquaculture systems, there is no question that average levels of biodiversity in ecosystems will continue to experience sharp declines in local biotic diversity, which eventually leads to losses in complexity that can, in turn, lead to transitions in ecosystem and Earth-system functioning that threaten all of humanity ([Rockstrom et al., 2009](#)). Fortunately, as our methods for studying and understanding the nature and significance of ecological complexity and biodiversity improve, solutions will emerge that can assure a sustainable future and avoid unwanted change in the functioning of our ecosystems or our crossing safe planetary boundaries.

Disturbance Regimes and the Historical Range of Variation in Terrestrial Ecosystems

Robert Keane, Missoula Fire Sciences Laboratory, Missoula, MT, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Disturbance regime Cumulative effects of disturbance events over space and time.

Ecosystem management Conservation of major ecological services and restoration of natural resources while meeting society's needs for current and future generations.

Ecosystem process Any exchange of matter or energy within an ecosystem.

Focal landscape Area being evaluated in an HRV analysis.

Historical range of variation (HRV) Expression of the full range of landscape characteristics that occurred in the past.

Mosaic Spatial patch distribution of vegetation communities.

Scale Temporal or spatial extent before some quantity of interest changes.

Simulation buffer Area surrounding the context landscape that allows for the spread of spatial processes into the context landscape.

Simulation landscape Area being simulated to produce an HRV time series that usually includes both the context landscape and the simulation buffer.

Succession Process of plant assemblages replacing another; vegetation development.

Disturbance Regimes

Picture a tranquil landscape with undulating topography, idyllic streams, scenic glades, and verdant vegetation. Left to its own devices, this landscape would gradually become dominated by late successional communities that would slowly shift in response to climate changes over long time periods. This scene often forms the foundation and reference for most land management across the globe. However, this peaceful panorama rarely happens in nature because gradual successional change rarely drives landscape dynamics. Abrupt change is usually the rule, with vegetation development suddenly truncated by a set of ecological processes more dynamic than succession: disturbance. A wide variety of insect, disease, animal, fire, weather, and even human disturbances can interact with current and antecedent vegetation and climate to perturb the landscape and create a shifting mosaic of diverse seral vegetation communities and stand structures that in turn affect those very disturbances that created them. This complex interaction of vegetation, climate, and disturbance results in unique landscape behaviors that foster a wide range of landscape characteristics, which ensures high levels of biodiversity. The impacts of disturbances on landscape pattern, structure, and function drive most ecosystem processes, and it is disturbances that ultimately set the bounds of management for most landscapes of the world. In this chapter, disturbance regimes are discussed in terms of how they affect landscape dynamics and how historical disturbance regimes can form the range and variation of possible landscape conditions that can be used as a reference for managing today's landscapes.

Background

"Disturbance regime" is a general term that describes the temporal and spatial characteristics of a disturbance agent and the impact of that agent on the landscape. More specifically, a disturbance regime is the cumulative effects of multiple disturbance events over space and time. Any description of a

disturbance regime must encompass an area that is large enough that the full range of disturbance sizes are manifest and with time measurement that is long enough that the full range of disturbance characteristics are captured. It is important to recognize that disturbance regimes are fundamentally different from individual disturbance events; for ecological restoration to succeed, for example, disturbance regimes should be emulated, not individual disturbance events, to fully capture the range and variation of disturbance effects. Biodiversity is intricately linked to disturbance regimes in that disturbances create shifting mosaics of diverse plant communities and habitats across a landscape (Watt, 1947), and the spatial and temporal fluctuations of these communities ensure the conservation of biodiversity (Naveh, 1994). Biodiversity is highest when disturbance is neither too rare nor too frequent on the landscape (Grime, 1973).

In this chapter, disturbance regimes can be generally described by 11 characteristics (Table 1) (Simard, 1996; Agee, 1993, 1998; Skinner and Chang, 1996). The disturbance "agent" is the entity that causes the disturbance, such as wind, fire, and beetles. Sometimes disturbance agents have a "source" that triggers the agent. Lightning can be a source for wildland fire, and heavy snow loads may be the source for avalanches. The disturbance agent occurs at a particular frequency that is often described over a period of time, depending on scale and objective. Point-level measures, such as disturbance return interval and occurrence probability, describe the number of disturbance events experienced over time at one point on the landscape (Skinner and Chang, 1996; Baker and Ehle, 2001). Spatial measures of disturbance rotation and disturbance cycle estimate the number of years it takes to disturb an area the size of the landscape (Johnson and Gutsell, 1994; van Wagner, 1978; Reed *et al.*, 1998). The frequency distribution of disturbance sizes on a landscape or region, for example, will depend primarily on the size and number of the largest events and landscape complexity (Yarie, 1981; Strauss *et al.*, 1989).

Table 1 The 11 terms used to describe disturbance regimes in this chapter from Agee (1993), Simard (1996), and Skinner and Chang (1996)

<i>Disturbance Characteristic</i>	<i>Description</i>	<i>Example</i>
Agent	Factor causing the disturbance	Mountain pine beetle is the agent that kills trees
Source, cause	Origin of the agent	Lighting is a source for wildland fire
Frequency	How often the disturbance occurs or its return time	Years since last fire or beetle outbreak (scale dependent)
Intensity	A description of the magnitude of the disturbance agent	Mountain pine beetle population levels; wildland fire heat output
Severity	The level of impact of the disturbance on the environment	Percent mountain pine beetle tree mortality; fuel consumption in wildland fires
Size	Spatial extent of the disturbance	Mountain pine beetles can kill trees in small patches or across entire landscapes
Pattern	Patch size distribution of disturbance effects; spatial heterogeneity of disturbance effects	Fire can burn large regions, but weather and fuels can influence fire intensity and therefore the patchwork of tree mortality
Seasonality	Time of year of that disturbance occurs	Species phenology can influence wildland fires effects; spring burns can be more damaging to growing plants than fall burns on dormant plants
Duration	Length of time of that disturbances occur	Mountain pine beetle outbreaks usually last for 3–8 years; fires can burn for a day or for an entire summer
Interactions	Disturbance interact with each other, climate, vegetation, and other landscape characteristics	Mountain pine beetles can create fuel complexes that facilitate or exclude wildland fire
Variability	The spatial and temporal variability of the above factors	Highly variable weather and mountain pine beetle mortality can cause highly variable burn conditions resulting in patchy burns of small to large sizes

Disturbance “intensity” is the level of the disturbance agent as it occurs on the landscape. Insect and disease intensities are often described by population levels. Wildland fire intensity is described by its heat output. Windthrow intensity can be described by wind speed. “Severity” is different from intensity in that it reflects the impact of that disturbance and its characteristics on the biophysical environment. The primary and direct effects of most disturbance agents are biotic damage and mortality, but some physical disturbances such as fire can act on abiotic factors such as soil fertility, necromass consumption, and atmospheric emissions. Most disturbance regimes are described by their cumulative severities because it is the most important factor that directly impacts land management.

The “sizes” (area) and “patterns” (spatial variability) of disturbance events also shape disturbance regimes and influence biodiversity. Distributions of disturbance sizes reflect critical features of a disturbance regime, and many think that disturbance size distributions support the theory that they are self-organized processes (Malamud, 1998; Ricotta *et al.*, 1999). Moreover, patterns of disturbance severity and intensity often dictate landscape heterogeneity, which influences a wide variety of landscape characteristics such as wildlife habitat, hydrology, biodiversity, and other disturbances (Turner, 1987; Knight, 1987; Gustafson and Gardner, 1996). “Pattern” refers to the size, shape, and spatial location of the perturbed patches. Seasonality is the time of year of the disturbance event because plant and animal phenology can produce differential spatial effects, and disturbance patterns are often linked with the “duration” of the disturbance agent on the landscape, with durations ranging from seconds (wind) and minutes (avalanches) to days (fire) and years (insects).

The last two terms are the most important and tend to cross over all other disturbance descriptive terminology. It is the “variability” of disturbance characteristics such as severity,

frequency, and size, coupled with the *interaction* of these characteristics with other disturbance characteristics such as previous patterns, duration, and seasonality, and climate that make disturbance regimes some of the most complex processes governing landscape dynamics and controlling biodiversity. It is this great complexity that confounds the description and classification of disturbance regimes into the simple abstractions often used in land management (Ryan and Noste, 1985). The highly variable spatial and temporal feedbacks and interactions of landscape patterns with disturbance characteristics and climate dynamics also make disturbance regimes so difficult to understand. It is far more illustrative to present the concept of disturbance regimes with an example from one of the world’s most ubiquitous disturbances – wildland fire (Bowman *et al.*, 2009).

Disturbance Regime Example: Wildland Fire

Wildland fire regimes generally result from the cumulative interaction of fire, vegetation, climate, humans, and topography over time (Crutzen and Goldammer, 1993), though there are many other factors that influence disturbance regimes (e.g., other disturbances, weather, and fuels) (Figure 1). These interactions are spatially and temporally correlated. Future fires are influenced in space by the pattern of previously burned stands, fire-prone topographic features (e.g., mid-slopes, riparian bottoms), and areas with high fuel accumulations (e.g., older stands). They are influenced in time by the timing and severity of past climate (e.g., drought, wind), the rate of vegetation development (e.g., succession), and the frequency of other disturbance events (e.g., previous fires, insect outbreaks). A change in any of these factors will ultimately result in a change in the fire regime, and because all factors are constantly changing, fire regimes are inherently dynamic. For

Figure 1 Four of the most important factors affecting fire regimes and their interactions.

example, climate change can affect fire regimes by altering fire ignition patterns (i.e., lightning), vegetation characteristics, and fuels (Flannigan and Van Wagner, 1991; Balling *et al.*, 1992; Swetnam, 1993). And exotic invasions such as white pine blister rust (*Cronarium ribicola*), cheatgrass (*Bromus tectorum*), and spotted knapweed (*Centaurea maculosa*), have changed fire regimes in many semiarid ecosystems of the US (Whisenant, 1990; Knapp, 1997).

Fire regimes are created by the interaction of bottom-up and top-down controls (Heyerdahl *et al.*, 2001). Bottom-up controls such as vegetation, fuels, topography, and patch distributions dictate fire spread, intensity, and severity at fine scales, and it is the bottom-up controls that can often be manipulated by land management. Coarse-scale, top-down controls are mostly climate and weather, which often dictate fire frequency, duration, and synchrony (Swetnam, 1990). Climate and weather trend signals are often embedded in a complex set of atmospheric teleconnections (simultaneous variations in climate observed over distant areas) interacting with land surface weather patterns. Drought-induced wildfires have been associated with global circulation anomalies such as the El Niño-Southern Oscillation (Swetnam and Betancourt, 1998; Heyerdahl *et al.*, 2002) and more recently the Pacific Decadal Oscillation (Hessl *et al.*, 2004). Coarse-scale, top-down climate interacts with fine scale landscape characteristics to influence the timing, size, frequency, and severity of fire events. As a result, a fire regime is actually a spatial disturbance gradient that does not follow discrete mapping units, so it should not be viewed as an attribute or characteristic of an ecosystem or cover type. Attempts to predict fire regimes solely from fuels (Olson, 1981), vegetation (Frost, 1998), or topography (Keane *et al.*, 2004b) have only partially succeeded because they did not recognize the spatial pervasiveness of fire on the landscape and the multiscale interactions of all factors that control fire dynamics (Morgan *et al.*, 2001).

The role of ignition in the formation of fire regimes is relatively misunderstood. Although fires can start from several

sources such as spontaneous combustion, volcanic eruptions, and sunlight magnification, two sources start most wildland fires – lightning and humans. Ignition patterns are quite different between lightning and humans, with lightning strikes being mostly randomly distributed across landscapes over long temporal scales (Fuquay, 1980; Van Wagtendonk, 1991). Historical and contemporary peoples, however, have tended to light more fires along major transportation routes and settlements. These ignition patterns can create different fire regimes, depending on the geographical location. Lightning strikes in moist, productive ecosystems rarely start a fire because the fuel is too wet most years and the lightning occurs in the seasons when fuel is the wettest (Barrows *et al.*, 1977; Fuquay, 1980). Humans, however, can start fires when the fuel is driest and can control the number and types of ignition.

Fire regimes are most often described in terms of severity and frequency (Agee, 1998; Heinselman, 1981) (Table 1) because these two factors are usually the most important to land management and also because these two characteristics are probably the most important factors in creating fire regimes. In general, species with fire-adapted survival traits such as thick bark, high crowns, and sprouting tend to dominate landscapes with frequent fires, whereas other fire-adapted traits such as serotiny, soil seed banks, and far-ranging dispersal become important as fires become less frequent (Grime, 1979; Connell and Slayter, 1977). Although the size, pattern, and shifting mosaic of fire severity can be quite complex, severity types are often grouped into three general categories: (1) nonlethal surface fires, (2) mixed-severity fires, and (3) stand-replacement fires. Nonlethal surface fires are usually frequent and burn surface fuels at low intensities, causing low mortality (<10%). Stand-replacement burns are usually rarer and reduce or kill the majority of the dominant vegetation, often trees and shrubs (90%) (Brown, 1995) as both lethal surface fires and active crown fires (Agee, 1993). Mixed-severity burns contain elements of both nonlethal surface and stand-replacement fires mixed in time and space (Arno *et al.*, 2000; Perry *et al.*, 2011). Passive crown fires, patchy stand-replacement fires, and low-intensity underburns are common in mixed-severity burns (DeBano *et al.*, 1998). Typically, mixed-severity fires are used to describe an area of patchy burn patterns created during one fire event. However, mixed-severity fire regimes can also be used to describe mixed-severity fires over time (e.g., nonlethal surface fire followed by stand-replacement fire) (Shinneman and Baker, 1997). There are other fire regime types, including ground fires (i.e., fire burning extensive organic layers), but they are not as prevalent as these three types (Agee, 1993).

Fire frequency and severity can be finely to broadly quantified using a number of field methods (Swetnam *et al.*, 1999; Humphries and Bourgeron, 2001; Heyerdahl *et al.*, 2001). Fire scar dates can be measured from trees, snags, stumps, and downed logs, but scarred trees are rarely distributed across large regions and diverse ecosystems at the densities needed to adequately describe fire regimes and corresponding landscape characteristics (Heyerdahl, 1997). Landscapes with long fire return intervals dominated by stand-replacement fire, for example, contain few fire-scarred trees. Charcoal samples from lake and ocean sediments and soil profiles provide important sources of historical fire data, but the temporal resolution of

the data is often inadequate for quantifying the annual variation in fire regimes (Whitlock and Millspaugh, 1996). Burn-boundary maps or fire atlases are another source for quantifying fire regimes, but these maps usually span a short temporal scale and rarely describe fire severity (Rollins *et al.*, 2001).

Perhaps the best way to illustrate the impact of a fire regime on the landscape is to describe a specific example from the high mountains of western North America (see **Box 1**). Whitebark pine (*Pinus albicaulis*) forests are declining across most of their range because of the combined effects of the modification of three disturbance factors (Arno, 1986). Furthermore, predicted changes in climate brought about by global warming could further exacerbate the decline by increasing the frequency and duration of beetle epidemics, blister rust infections, and severe wildfires (Logan and Powell, 2001; Running, 2006). The loss of whitebark pine could have serious consequences for the biodiversity of upper subalpine ecosystems because it is considered a keystone species (Tomback *et al.*, 2001). This “stone” pine produces large, wingless seeds that are an important food source for more than 110 animal species (Hutchins, 1994). In the Yellowstone ecosystem, the endangered grizzly bear (*Ursus arctos horribilis*) depends on whitebark pine seeds as a major food source, which it raids from red squirrel (*Tamiasciurus hudsonicus*) middens.

One major goal of ecosystem management, especially in the case of whitebark pine restoration, is to emulate historical disturbance regimes on contemporary landscapes to promote those processes that were considered necessary for healthy ecosystems. However, as is evident from the previous discussions, the complexity, interactions, and variability of disturbance regimes makes implementing historical disturbance regimes difficult if not impractical. An easier and more straightforward method of assessing ecosystem condition and evaluating ecosystem health was needed. The variability of historical disturbance regimes on landscape dynamics provided a foundation for a novel method of assessing ecosystem condition.

Historical Range and Variation

The Background

To effectively implement ecosystem management, land managers found it necessary to obtain a reference or benchmark to represent the conditions that described fully functional ecosystems (Cissel *et al.*, 1994; Laughlin *et al.*, 2004). Contemporary conditions could be evaluated against this reference to determine status, trend, and magnitude of change and also to design treatments that provide society with its sustainable and valuable resources while also returning declining ecosystems to a more natural or sustainable condition (Hessburg *et al.*, 1999b; Swetnam *et al.*, 1999). Ecologists and land managers were beginning to recognize that landscapes were not static but constantly changing, so it was critical that these reference conditions represented the dynamic character of ecosystems and landscapes as they vary over time and across space (Watt, 1947; Swanson *et al.*, 1994). Describing and quantifying ecological health has always been difficult because ecosystems are highly complex, with immense biotic and

Box 1 Whitebark pine ecology, management, and HRV

Whitebark pine is a long-lived, seral tree of moderate shade tolerance that can live well beyond 400 years (one tree is more than 1300 years), and on many sites it is eventually replaced, in the absence of fire, by the shade-tolerant subalpine fir (*Abies lasiocarpa*), with minor amounts of spruce (*Picea engelmannii*) and mountain hemlock (*Tsuga mertensiana*) in the mesic parts of its range (Arno and Hoff, 1990; Keane, 2001). Clark's nutcracker (*Nucifraga columbiana*) plays a critical role in the dispersal of whitebark pine's heavy, wingless seed (Tomback, 1998; Lorenz *et al.*, 2008) (**Photo 1**). The bird harvests seed from purple cones during late summer and early fall and carries as many as 100 of them in a sublingual pouch to sites as far as 10–20 km away, where it buries as many as 15 seeds in caches 2–3 cm below the soil surface. Seeds that remain unclaimed eventually germinate and grow into whitebark pine trees (Tomback, 2005). Nutcrackers often cache in open areas with a high degree of ground pattern in high-mountain settings that are often created by wildland fire (Morgan and Bunting, 1989).

Photo 1 Clark's nutcracker harvesting seeds from a whitebark pine (Photo by D. Tomback).

Three types of fires describe the diverse fire regime that occurs in whitebark pine forests (Morgan and Bunting, 1989; Murray *et al.*, 1998). Some high elevation whitebark pine stands experience nonlethal surface fires because sparse fuel loadings and widely spaced trees foster low-intensity fires (Keane *et al.*, 1994). The more common, mixed-severity fire regime is characterized by fires of mixed severities in space and time, creating complex mosaics of tree survival and mortality on the landscape (Murray, 2008; Arno and Weaver, 1990). Burned patches are important caching habitat for Clark's nutcracker because it prefers to cache in nearby burned patches, probably because of the heavy seeds (Norment, 1991). Many whitebark pine forests in Montana, northern Idaho, and the Cascades originated from large stand-replacement fires that occurred at long time intervals (greater than 250 years) where nutcrackers cache whitebark pine great distances (Keane *et al.*, 1994; Murray, 2008). The great variability in historical fire severity, frequency, pattern, and size has ensured the continued dominance of whitebark pine on upper subalpine landscapes in western North America.

disturbance variability and diverse processes interacting across multiple space and time scales from genes to species to landscapes, and from seconds to days and centuries. One central concern with implementing ecosystem management was identifying appropriate reference conditions that could be used to describe ecosystem health, prioritize those areas in decline for possible treatment, and design feasible treatments for restoring their health (Aplet *et al.*, 2000).

The relatively new concept of historical range and variability (HRV) was introduced in the 1990s to bring understanding of past spatial and temporal variability into ecosystem management (Cissel *et al.*, 1994). HRV provided land-use planning and ecosystem management a critical spatial and temporal foundation to plan and implement possible treatments to improve ecosystem health and integrity (Landres *et al.*, 1999). Why not let recent history be a yardstick to compare ecological status and change by assuming that recent historical variation represents the broad envelope of conditions that supports landscape resilience and its self-organizing capacity (Hessburg *et al.*, 1999b)? Managers initially used “target” conditions developed from historical evidence to craft treatment prescriptions and prioritize areas (Harrod *et al.*, 1999). However, these target conditions tended to be subjective and somewhat arbitrary because they represented only one possible situation from a wide range of conditions that could be created from historical disturbance and vegetation dynamics (Keane *et al.*, 2002). This single objective, target-based approach was then supplanted by a more-comprehensive theory of HRV that incorporated the full variation and range of conditions that occurred across multiple scales of time and space into a metric of ecosystem health.

The idea of using historical conditions as reference for land management is not new (Egan and Howell, 2001). Since the 1990s planners have been using target stand and landscape conditions that resemble historical analogs to guide landscape management, and research has provided various examples (Christensen *et al.*, 1996; Fulé *et al.*, 1997; Harrod *et al.*, 1999). However, the inclusion of temporal variability of ecosystem elements into land management has only recently been employed. Landres *et al.* (1999) presented some of the theoretical underpinnings behind HRV and extensive reviews, and other background material on HRV and associated terminology can also be found (Egan and Howell, 2001; Swanson *et al.*, 1994; Kaufmann *et al.*, 1994; Morgan *et al.*, 1994; Foster *et al.*, 1996; Millar, 1997; Aplet and Keeton, 1999; Hessburg *et al.*, 1999a; Perera *et al.*, 2004; Veblen, 2003). This section was taken from material in Keane *et al.* (2009). The major advancement of HRV over the historical target approach is that the full range of historical ecological characteristics is used as the critical criterion in the evaluation and management of ecosystems (Swanson *et al.*, 1994). It is this variability that ensures continued health, self-organization, and resilience of biodiversity, ecosystems, and landscapes across spatiotemporal scales (Holling, 1992). Understanding the causes and consequences of this variability is key to managing landscapes that sustain ecosystems and the services they offer to society.

The Concept

The theory behind HRV is that the broad historical envelope of possible ecosystem conditions such as burned area, vegetation cover type area, and patch size distribution can provide a representative time series of reference conditions to guide land management (Aplet and Keeton, 1999) (see Figure 2 as an example). This theory assumes the following: (1) Ecosystems are dynamic, not static, and their responses to changing processes are represented by past variability (Veblen, 2003); (2)

Figure 2 An example of a simulated time series for southwestern Montana, USA, mountainous landscape showing the five most dominant succession communities for simplicity. Also shown are the simulated average and the composition of the current landscape with only one succession class present (Keane *et al.*, 2008).

ecosystems are complex and have a range of conditions within which they are self-sustaining, and beyond this range they transition to disequilibrium (Egan and Howell, 2001; Wu *et al.*, 2006); (3) historical conditions can serve as a proxy for ecosystem health (Swetnam *et al.*, 1999); (4) the time and space domains that define the HRV are sufficient to quantify observed variation (Turner *et al.*, 1993); and (5) the ecological characteristics being assessed for the ecosystem or landscapes match the management objective (Keane *et al.*, 2002). In this chapter, we will focus the discussion on historical variations of landscape, not stand dynamics, and specifically landscape composition (i.e., aerial extent of vegetation communities) and structure (i.e., patch distributions).

Any quantification of HRV requires an explicit specification of the spatial and temporal context. The spatial context is needed to ensure that the variation of the selected landscape attribute is described across the most appropriate area relative to the spatial dynamics of ecosystem or landscape processes. The variability of the area occupied by a vegetation type over time, for example, generally decreases as the spatial context increases until it reaches an asymptote, which can be used to approximate optimal landscape size (Fortin and Dale, 2005; Karau and Keane, 2007). The optimal size of evaluation area will depend on (1) the ecosystem attribute evaluated, (2) the dynamics of major disturbance regimes, and (3) the relevant management issues (Tang and Gustafson, 1997). Fine woody fuel loadings, for example, would vary across smaller scales than coarse woody debris loads (Tinker and Knight, 2001).

The time scale over which HRV is evaluated must also be specified to properly interpret the underlying biophysical processes that influenced historical ecosystem dynamics,

especially climate (Millar and Woolfenden, 1999). The HRV of landscape composition evaluated from 1300 to 1600 AD might be entirely different if evaluated from 1600 to 1900 AD because of the vast differences in climates and land use between those periods (Mock and Bartlein, 1995). Temporal scale and resolution is usually dictated by the temporal depth of the historical evidence used to define and describe HRV, but they can also be selected to match specific management objectives. These time and space scale constraints are both a benefit and limitation of the HRV concept.

One advantage of the HRV approach is that it can use many elements to describe ecosystems, stands, or landscapes at any scale (Egan and Howell, 2001). The HRV of tree basal area, for example, can be assessed at the stand, landscape, and regional spatial scales; similarly, the HRV for landscape composition and patch structure can be computed for a watershed, National Forest, or an entire region. This multiscaled, multi-characteristic approach allows HRV attributes to be matched to the specific land management objectives at their most appropriate scale. For instance, fuel managers might decide to evaluate the HRV of coarse woody fuels and severe fire behavior at a watershed level (Hessburg *et al.*, 2007) to manage landscapes for continued ecological integrity and high biodiversity. Similarly, each HRV element can be prioritized or weighed based on its importance to the land management objective. This forms the critical linkage to adaptive land management in which iterative HRV analyses can be used to balance trade-offs in landscape integrity of ecosystems with other social issues and economic values. Perhaps the biggest advantage of HRV is that it forced land managers to recognize the dynamic character of landscapes in crafting management plans (Keane *et al.* 2009).

Its Application

HRV has been used in many land management projects. The departure of current conditions from historical variations have been used to prioritize and select areas for possible restoration treatments (Reynolds and Hessburg, 2005; Hessburg *et al.*, 2007) or to identify areas to conserve biological diversity (Aplet and Keeton, 1999). US fire management agencies have used fire regime condition class (FRCC), which is based on HRV of fire and vegetation dynamics, to rate and prioritize lands for fuel treatments (Hann and Bunnell, 2001; Schmidt *et al.*, 2002; Hann, 2004) (<http://www.frcc.gov>). The HRV of patch size and contagion was demonstrated to design the size of treatment area and landscape composition to select the appropriate management treatments to mimic patch characteristics (Keane *et al.*, 2002). Keane *et al.* (1996) used the HRV approach to design coarse-scale restoration of the previously discussed whitebark pine ecosystem in the Pacific Northwest.

Reference conditions for HRV have been described for many ecosystems across the western US and Canada. Veblen and Donnegan (2005) synthesized available knowledge on forest conditions and ecosystem disturbance for national forest lands in Colorado, USA. The ecological and economic implications of forest policies designed to emulate historical fire regimes were investigated by Thompson *et al.* (2006) using a simulation approach. Historical vegetation and disturbance

dynamics for southern Utah were summarized in the Hood and Miller (2007) report. Wong *et al.* (2003) compiled an extensive reference of historical disturbance regimes for the entire province of British Columbia, Canada. Several studies have detailed historical variations in upland vegetation for two national forests in Wyoming (Dillon *et al.*, 2005; Meyer *et al.*, 2005). Although these studies are good qualitative references for understanding and interpreting historical conditions, they do not provide the quantitative detail needed to implement the described reference conditions directly into management applications.

Quantification of HRV demands temporally deep and spatially explicit historical data. Data sets that represent long-term empirical landscape dynamics are rarely available, inconsistent, and difficult to obtain (Humphries and Bourgeron, 2001; Barrett *et al.*, 2006). Historical reconstructions of landscape characteristics can be made from many sources if they exist for a particular landscape (see Egan and Howell, 2001, for a summary). Historical vegetation conditions can be reconstructed or described from (1) pollen deposits in lake or ocean sediments; (2) plant macrofossil assemblages deposited in middens, sediments, soils, and other sites; (3) dendrochronological stand reconstructions and fire scar histories; (4) land survey records; and (5) repeat photography (Gruell *et al.*, 1982; Arno *et al.*, 1995; Humphries and Bourgeron, 2001; Friedman *et al.*, 2001; Montes *et al.*, 2005; Schulte and Mladenoff, 2005). Unfortunately, these data have either a confined or unknown spatial domain because they were collected on a very small portion of the landscape, or they pertain to a broad, undefined area (middens, lake sediments) and lack spatial specificity with respect to patterns. Moreover, some ecosystems on a landscape have little evidence of past conditions with which to quantify HRV, and any available data are usually limited in temporal extent. In general, those methods that describe HRV at fine time scales, such as tree fire scar dating, are constrained to multi-centenary time scales, whereas those methods that cover long time spans (millennia), such as pollen and charcoal analyses, have a resolution that may be too coarse for management of spatial patterns of structure and composition (Swetnam *et al.*, 1999).

For most landscape-level HRV quantification, there are three main sources of spatial data to quantify historical conditions (Keane *et al.*, 2006; Humphries and Bourgeron, 2001). The best sources are spatial chronosequences or digital maps of historical landscape characteristics over many time periods. Unfortunately, temporally deep and spatially explicit time series of historical conditions are missing for many US landscapes because aerial photography and satellite imagery are rare or were nonexistent before 1930 AD and comprehensive maps of forest vegetation are scarce, inconsistent, and limited in coverage prior to 1900. Tinker *et al.* (2003) quantified HRV in landscape structure using digital maps of current and past landscapes in the Greater Yellowstone Area from aerial photos and stand age interpretation.

Another HRV data source is to substitute space for time and collect spatial data across similar landscapes, from one or more times, across a large geographic region (Hessburg *et al.*, 1999a, 1999b). This assumes landscapes of similar biophysical environments with similar disturbance and climatic

regimes can provide a representative cross section of temporal variation of landscape dynamics. In effect, differences in space are equivalent to differences in time, and inferences may be drawn regarding variation in spatial pattern that might occur at a single location over time. However, subtle differences in landform, relief, soils, and climate make each landscape unique, and grouping landscapes may tend to overestimate range and variability of landscape characteristics (Keane *et al.*, 2002). Landscapes may be similar in terms of the processes that govern vegetation such as climate, disturbance, and species succession, but topography, soils, land use, and wind direction also influence vegetation development and fire growth (Knight, 1987).

A third approach for quantifying HRV involves using computer models to simulate historical dynamics to produce a time series of simulated data to compute HRV statistics and metrics. This approach relies on the accurate simulation of succession and disturbance processes in space and time (Keane *et al.*, 2002a). Many spatially explicit ecosystem simulation models are available for quantifying HRV patch dynamics (Gardner *et al.*, 1999; Mladenoff and Baker, 1999; Humphries and Baron, 2001; Keane *et al.*, 2004a), but most are (1) computationally intensive, (2) difficult to parameterize and initialize, and (3) overly complex, thereby making them difficult to use, especially for large regions, long time periods, and inexperienced staffs. However, those landscape models designed specifically for management planning may oversimplify vegetation development and disturbance. Even the most complex landscape models rarely simulate spatial interactions between climate, fire dynamics, and vegetation development at the scales needed to quantify HRV because of the lack of critical research in those areas and the immense amount of computer resources required for such an effort. Even with its shortcomings, simulation modeling is the most common method of creating HRV time series, and many studies have used simulation modeling to quantify HRV time series for landscapes and ecosystems using a wide variety of models. Nonspatial models such as VDDT (Beukema and Kurtz, 1995) were used to estimate landscape composition in a wide variety of areas from the Pacific Northwest to the northern Rocky Mountains (Hann *et al.*, 1997; Barbour *et al.*, 2007; Kurz *et al.*, 1999). The LADS model (Wimberly *et al.*, 2000) was used for the Oregon Coast Range to determine the appropriate level of old growth forests to quantify HRV in landscape structure (Nonaka and Spies, 2005), and to simulate the effect of forest policies (Thompson *et al.*, 2006). McGarigal *et al.* (2003) quantified historical forest composition and structures of Colorado landscapes. Keane *et al.* (2002) simulated historical landscape patch dynamics using the LANDSUM model for northern Rocky Mountain USA landscapes. The LANDFIRE prototype project quantified historical time series for landscapes across the US using the LANDSUM model (Keane *et al.*, 2007) (Figure 3).

There is a common misconception that long-term simulation model HRV outputs are inappropriate because the simulation of fire and landscape dynamics occurred while unrealistically holding climate and fire regimes constant (Keane *et al.*, 2006). This would be true if the objective of the modeling were to replicate historical fire events. However, the

primary purpose of HRV modeling efforts is to describe variation in historical landscape dynamics, not to replicate them. Simulation modeling allows the quantification of the entire range of landscape conditions by simulating the static historical fire regime for long time periods (e.g., thousands of years) to ensure all possible fire ignitions and burn patterns are represented in the HRV time series. In contrast, HRV time series from empirical historical records will tend to underestimate variation of landscape conditions because there are a limited number of fire events in the historical record. Model input parameters represent the actual temporal context, whereas the simulation time represents the length of time needed to adequately capture the range and variation of historical conditions. Because the temporal domain of model parameters often represents only four or five centuries, it may seem that only 500 years of simulation are needed. However, the parameters quantified from sampled fire events that occurred during this time represent only one unique sequence of the fire ignitions and growth that created the unique landscape compositions observed today. If these events happened at different times or in different areas, an entirely different set of landscape conditions would have resulted.

Its Limitations

Although easily understood, the concept of HRV can be quite difficult to implement due to scale, data, and analysis limitations (Wong and Iverson, 2004). Inappropriate temporal and spatial scales to evaluate landscapes will introduce bias and increased variability into the computation of HRV statistics because the scales of climate, vegetation, and disturbance interactions are inherently different across landscapes (Morgan *et al.*, 1994). Karau and Keane (2007) found that simulated HRV chronosequences of landscapes smaller than 100 km² had increased variability in landscape composition due to the truncated spatial dynamics of simulated disturbance processes as they ran into the landscape boundary. This is why HRV approaches are inappropriate when applied on small areas such as stands. A Douglas-fir stand that was historically dominated by ponderosa pine, for example, may appear to be outside HRV, but if it is within a 100-km² landscape composed primarily of ponderosa pine, it will certainly be within HRV. However, when evaluation landscapes are large (> 500 km²), it is often difficult to detect significant changes caused by ecosystem restoration or fuel treatments implemented on small areas (Keane *et al.*, 2006). There is an optimal landscape extent for HRV simulation, but this optimum depends on subtle differences in topography, climate, and vegetation across large regions, and it also changes with spatial resolution.

There are few statistical techniques to compare HRV time series data to current landscape composition and structure (Figure 2). Many have used departure statistics to describe the dissimilarity of current conditions from historical variations to prioritize and select areas for possible restoration treatments (Reynolds and Hessburg, 2005; Hessburg *et al.*, 2007) or areas to conserve biological diversity (Aplet and Keeton, 1999). These departure methods use the similarity metrics from landscape and community ecology to estimate departure from

Figure 3 The computation of departure from HRV used in the LANDFIRE project (Keane *et al.* 2007). A simulated historical landscape composition time series is created using the LANDSUMv4 model for a landscape reporting unit (focal landscape). This time series is then compared to current conditions using an ecological similarity analysis to compute fire regime condition class (FRCC). FRCC is a three-category ordinal index reflecting the degree of departure from historical conditions, with red indicating areas where the landscapes are the most departed.

HRV, and most have limitations when used in HRV applications (Keane *et al.*, 2011) (Figure 3). For example, the Sorenson's index is sensitive to the number of classes used to describe the landscape (Keane *et al.*, 2008, 2011). Furthermore, some departure indices are insensitive to subtle changes in landscape composition when the same categories appear in all time sequences. Better multivariate statistical techniques with hypothesis testing are needed for more-credible HRV analyses.

Many limitations are associated with the use of the simulation approach to quantify HRV (Keane *et al.*, 2011). It is impossible to build a model that includes all those landscape and ecosystem processes that directly affect those variables selected to represent the HRV time series. Information and data concerning the important processes and their linkages used to construct models is often inadequate. And, as model complexity increases, so does instability, computational requirements, input parameters, and reliability; there is a trade-off between model complexity and applicability. Simple, empirical modeling approaches are easier to understand and yield the most accurate answers, but they are limited in scope, data intensive, and often incapable of directly simulating complex interactions. Mechanistic modeling approaches include greater detail in simulating ecological processes, making them more robust and comprehensive; these models, however, can be inaccurate, difficult to use, and somewhat unstable. There is also a lack of sufficient expertise and input parameter data to parameterize and execute most models, and it is difficult to test and validate models because there are few spatial historical time series that are temporally deep and in the right context for comparison with model results (Keane and Finney, 2003). As a result, the simulated variation also includes undesirable and unquantifiable sources such as unintended stochasticity, model flaws, inadequate parameterization, and oversimplifications. No single model will satisfy the varied HRV demands of management, so compromises in simulation design must always be made. The best model might not be the most useful because (1) few people know how to run the model, (2) there may be insufficient computer resources (software, hardware requirements) to run the model, and (3) there may be insufficient field data for input parameter approximation to run the model. Most HRV simulation projects are designed around the people responsible for their completion.

One major problem in defining landscapes for HRV quantifications is that the landscape edges create artificial boundaries across which spatial processes such as seed dispersal and wildland fire spread cannot traverse. Areas near the edge of the landscape, for example, have a limited number of surrounding pixels from which a seed can fall or a fire can spread into them (Figure 4). Spatial processes such as fires cannot immigrate into the simulation landscapes, resulting in decreased occurrence near landscape edges. This problem is exacerbated by biophysical processes such as fire, seed dispersal, and insect migrations that are controlled by directional vectors such as wind that differentially act on parts of a landscape. Areas downwind, for example, have a higher probability of burning than those upwind (Keane *et al.*, 2002a). The best way to mitigate the edge effects is to surround the simulation landscape with a buffer (Figure 4). Each

landscape is unique, so buffer width may differ for each setting. HRV simulations should be inspected to determine if the buffer is large enough to minimize edge effects within the context landscape, keeping in mind that simulation time increases exponentially as landscapes get larger.

The shape of the focal landscape is also an important factor in the simulation of HRV landscape dynamics. Fire frequencies in long, thin landscapes, for example, tend to be underestimated because simulated fires rarely reach their full size because they reach the landscape boundary first. Even with a large buffer, simulated fires spread quickly across a thin context landscape and burn only a fraction of its full size. Keane *et al.* (2002a) found fire frequencies were approximately 20–40% less in long landscapes with high edge. Many like to use watersheds to define simulation landscapes, but watersheds are often long and linear with high edge, making them somewhat undesirable for HRV simulation. The best shapes are squares, rectangles or circles that are large enough to contain both the buffer and context landscapes. The directional orientation of the simulation landscape is also important. Long, thin landscapes that are oriented perpendicular to the wind direction will have far less burned area over time than the same landscapes oriented parallel to the wind (Keane *et al.*, 2002a). The orientation is especially important if elongated landscapes are positioned at right angles to the wind direction; they will tend to have significantly less fire and narrow HRV time series.

Perhaps the most important limitation of the HRV application is that it may no longer be a viable concept for managing lands in the future because of expected climate warming and increasing contemporary human activities across the landscape (Millar *et al.*, 2007). Tomorrow's climates might change so rapidly and dramatically that they will no longer be similar to historical climates that created past conditions, and the continued spread of exotic plants, diseases, and other organisms by human transport will permanently alter ecosystems. Climate warming is expected to trigger major changes in disturbance processes, plant and animal species dynamics, and hydrological responses (Botkin *et al.*, 2007; Schneider *et al.*, 2007) that may create new plant communities, change biodiversity assemblages, and alter landscapes where they will be quite different from historical analogs (Notaro *et al.*, 2007). Whitebark pine, for example, is predicted to significantly decline under new forecast climates, so does it make sense to restore the species on landscapes where they are predicted to be reduced? Therefore, it may seem obvious that using historical references may no longer be reasonable in this rapidly changing world. However, a critical evaluation of possible alternatives may indicate that HRV, with all its faults and limitations, might be the most viable approach for the near term because it has the least amount of uncertainty.

One other alternative to HRV is to forecast the future variations of landscapes under changing climates using highly complex spatial, empirical, and mechanistic models, and this option is fraught with compounding uncertainties. The range of predictions for future climate from the major general circulation models may actually be greater than the variability of climate over the past two or three centuries (Stainforth *et al.*, 2005). This uncertainty increases when we factor in society's

Figure 4 Illustration of the edge effect when simulating fire regimes across landscapes and mitigation of this effect through the inclusion of a buffer in the simulation landscapes.

projected responses to climate change through technological advances, behavioral adaptations, and population growth (Schneider *et al.*, 2007). Moreover, the variability of climate extremes, not the gradual change of average climate, will drive

most ecosystem response to the climate-mitigated disturbance and plant dynamics, and these extreme events are the most difficult to predict (Easterling *et al.*, 2000, Smith, 2011). Uncertainty will also increase as the climate predictions are

extrapolated to the finer scales and longer time periods that are needed to quantify future range and variation (FRV) for landscapes. And this uncertainty will surely increase as we try to predict how ecosystems will respond to this simulated climate change (Araujo *et al.*, 2005). Mechanistic and empirical ecological models that simulate climate, vegetation, and disturbance dynamics across landscapes are often missing detailed representations and interactions of disturbance, hydrology, land use, and biological processes that will catalyze most climate interactions (Notaro *et al.*, 2007). Moreover, little is known about the interactions of climate with critical plant and animal life-cycle processes, especially reproduction and mortality (Keane *et al.*, 2001; Gworek *et al.*, 2007; Ibanez *et al.*, 2007; Lambrecht *et al.*, 2007), yet these process could be the most important in determining species response to climate change (Price *et al.*, 2001). Given large cumulative uncertainties involved in predicting future climates and subsequent ecosystem responses, it may be that HRV time series may have significantly lower uncertainty than any simulated predictions for the future. Recall that large variations in climates of the past several centuries are already reflected in the parameters used to simulate HRV time series. So before throwing the HRV baby out with the climate change bathwater, it may be more prudent to wait until simulation technology has improved enough to create credible FRV landscape pattern and composition time series for regional climate forecasts based on extensive model validation and testing, and this may take decades. In the meantime, it is doubtful that the use of HRV to guide management efforts will result in inappropriate activities considering the large genetic variation in most species (Rehfeldt *et al.*, 1999; Davis *et al.*, 2005).

In conclusion, the concept of HRV has a valid place in land management, at least for the near future. Landscape models can be used to simulate fire regimes and their interaction with climate and vegetation to create HRV time series that can be used as reference conditions to assess, plan, evaluate, design, and implement ecosystem-restoration treatments. HRV should be used to guide land management and not as a target on which to evaluate success or failure. There are few measures of ecosystem health that match the scale, scope, flexibility, and robustness of HRV analysis.

Glossary

Carrying capacity Usually defined as the average maximum number of individuals of a given species that can occupy a particular habitat without permanently impairing the productive capacity of that habitat.

Competitive exclusion The displacement of one species from its habitat or ecological niche by another. When humans appropriate other species' ecological space, it often leads to the local or even the global extinction of the nonhuman organism.

Ecological deficit An ecological deficit exists when the load imposed by a given human population on its own territory or habitat (e.g., region, country) exceeds the productive capacity of that habitat. Under these circumstances, if it wishes to avoid permanent damage to its local ecosystems, the population must use some biophysical goods and services imported from elsewhere (or, alternatively, lower its material standards).

Human load The total human load imposed on the environment by a specified population is the product of population size times average per capita resource consumption and waste production. The concept of load

recognizes that human carrying capacity is a function not only of population size but also of aggregate material and energy throughput. Thus, the human carrying capacity of a defined habitat is its maximum sustainability supportable load.

Overshoot A population is in overshoot when it exceeds available carrying capacity. A population in overshoot may permanently impair the long-term productive potential of its habitat, reducing future carrying capacity. It may survive temporarily but will eventually crash as it depletes vital natural capital (resource) stocks.

Patch disturbance The measurable habitat and ecosystem modification caused by large animals, including humans, as they forage for food or other resources. Patch disturbance is most pronounced near the den site, temporary camp, or other central place within the overall home range of the individual or group.

Sustainability gap The global ecological deficit – that is, the difference between any excessive human load on the ecosphere and the long-term carrying (or load-bearing) capacity of the planet.

Ecological footprint analysis (EFA) is a quantitative tool that represents the ecological load imposed on the earth by humans in spatial terms. Thus, the ecological footprint (EF) of a defined population is the total area of land and water ecosystems required to produce the resources that the population consumes, and to assimilate the wastes that the population generates, wherever on earth the land/water are located. Ecofootprinting is used to assess the ecosystem area effectively appropriated in support of any specified human population or economic activity. We can then compare this with available productive area (i.e., load-bearing capacity). The size and nature of the human EF is relevant to biodiversity conservation because energy and material resources extracted from nature to serve human purposes are irreversibly unavailable to other species. The larger the human footprint, the less the nonhuman biodiversity. This article describes the contemporary context for ecofootprint analysis and the theory on which it is based. It then discusses the implications of the analysis for sustainable development in general and for the future of biodiversity in particular.

The Conceptual Framework: Why Do We Need Ecofootprint Analysis?

Human Activity and Global Ecological Change

There is agreement among scientists that humanity has assumed a major role in changing the face of the earth. Up to

one-half of the land has been directly transformed by human action; more than half of the planet's accessible fresh water is already being used by humans; atmospheric carbon dioxide has increased from 280 to 393 parts per million (40%) during the industrial era and the resultant climate change is increasingly being accepted as a fact; more atmospheric nitrogen is fixed and injected into terrestrial ecosystems by humans than by all natural terrestrial processes combined; two-thirds of the world's major fisheries are fully or overexploited; and biodiversity losses are accelerating (Hansen *et al.*, 2010; Lubchenco, 1998; NOAA, 2011; Vitousek *et al.*, 1997).

What is in dispute is whether any of this really matters to socioeconomic sustainability. The more pessimistic analysts see human domination of the earth and the deterioration of nature as ultimately fatal to civilization itself. Various mechanisms are invoked in coming to this conclusion. For example, because of our culture's dependence on liquid petroleum and the present lack of affordable substitutes, energy analyst Richard Duncan (1993) argues that the total life expectancy of western technoindustrial society is less than 100 years – counting from the 1930s! (Significantly, the International Energy Agency conceded in 2010 that global production of conventional crude oil peaked in 2006, and is now in decline (EIA, 2010).) Hern attacks industrial culture's obsession with growth and compares humanity with a self-destructive cancer on the planet. The continuous expansion of the human enterprise apparently “exhibits all four major characteristics of a malignant process: rapid uncontrolled growth; invasion and

destruction of adjacent tissues (ecosystems, in this case); metastasis (colonization and urbanization, in this case); and dedifferentiation (loss of distinctiveness in individual components)" (Hern, 1997). According to geographers Smith and Sauer-Thompson, environmental decay, coupled with geopolitical stresses induced by resource scarcity, will inevitably cause industrial society to "self-destruct, producing massive ecological damage, social chaos, and mega-death" (Smith and Sauer-Thompson, 1998). From these perspectives, the human enterprise has already overshot global carrying capacity, is eroding future options, and will inevitably crash – there is virtually nothing we can do to prevent the collapse of global civilization.

At the other extreme, we can take comfort in the views of those scientists and economists who believe that human ingenuity will prevail. Their logic is simple. Stimulated by incipient scarcity, rising prices, and the opportunity for profit, scientists and entrepreneurs will find technological substitutes for exhaustible resources and natural processes. As energy economist Gordon explains, "the tendency to technical progress is viewed as the most critical economic law involved." Moreover, because human ingenuity has historically been remarkable at increasing living standards and warding off the pressures of resource depletion, "the immediate need for avoiding depletion is nil" (Gordon, 1994).

Perhaps the most extreme expression of this belief is revealed in the ebullient optimism of the late Julian Simon, who wrote: "Technology exists now to produce in virtually inexhaustible quantities just about all the products made by nature" and "We have in our hands now ... the technology to feed, clothe, and supply energy to an ever-growing population for the next seven billion years" (Simon, 1995). Inspired by Simon, Danish statistician Bjørn Lomborg, in *The Skeptical Environmentalist*, dismissed concerns about population growth, potential resource shortages, and pollution as being unsupported by the data (Lomborg, 2001). Some conventional economists even argue the benefits of continuous population growth on grounds that "additional people can create more resources than they use up, thanks to technological improvements" (Block, 1990). Clearly, from the techno-optimists' perspective, there are no practical limits at all on human carrying capacity – we do not need to do anything to sustain global civilization but stay our present, increasingly market-driven, global development course.

With such diametrically opposing assessments of the human prospect, both starting from present circumstances and held with equal conviction, it is little wonder that ordinary citizens and policy makers alike are confused about global ecological change and what – if anything – to do about it. This article assesses the overall sustainability conundrum using EF analysis and links the general problem to the specific issue of biodiversity conservation. First, however, we examine the origins of the ongoing perceptual conflict.

Evolving Economic Paradigms

Many of the conflicting views about sustainable development can be traced to differing fundamental beliefs, values, and assumptions about the nature of reality, particularly

humankind–environment relationships. The fact is that human beings socially construct their perceptions of reality (Berger and Luckmann, 1966). Different societies and interest groups therefore possess quite different conceptual lenses (worldviews, narratives, preanalytic visions, and paradigms) through which their members interpret new data, assertions, or circumstances. This is no trivial observation – group members may vigorously defend existing perceptions against contrary data, even though, as social constructs, their perceptions may be only tenuously connected to reality.

Remarkably, people are often unaware that they possess a particular worldview – each person acquires his or her culturally specific narrative unconsciously, simply by growing up in a particular socio-cultural milieu. We may therefore be unconscious of the subtle ways in which the prevailing worldview shapes our approach to critical issues or that there may be more viable alternatives. When we think that "the world is flat" was once accepted as self-evident truth, it raises the unsettling possibility that much of our present cultural worldview consists largely of shared illusions.

The dominant social paradigm in western (and increasingly global) technoindustrial capitalist culture can be characterized as the expansionist or the cornucopian worldview. As we have already seen, its strictest adherents believe that humankind has achieved mastery over the natural world and that technology, abetted by market processes, will be able to compensate for the depletion of natural resources and the loss of life-support services.

The economics of this expansionist vision is the neo-classical (neoliberal) economics that has come to dominate geopolitics in the past 50 years. The starting point for neoliberal analysis is the circular flow of exchange value in which money recycles repeatedly between producer firms (as payment for goods and services) and consumer households (as wages, salaries, and returns on investment). This model portrays the economy as a self-renewing, self-feeding perpetual motion machine, as an isolated system with no inlets or outlets to anything outside itself; the economy floats free of the natural world, its productivity and growth unconstrained by biophysical limits. Because conventional economics treats the economy as separate from, and essentially independent of, the environment, development policy has historically treated humans solely as economic agents.

While still dominant in policy circles, the neoliberal perspective as described is increasingly being challenged. The accelerating pace of global change, including an alarming accumulation of market externalities, has convinced many mainstream economists of the need to reconsider the implications of unlimited growth, to acknowledge the complex dynamics of de facto world economy–ecosystems relationships, and to address the failures of market prices to reflect real environmental and social costs (e.g., Arrow et al., 1996).

The most 'out-of-the-box' critique of the mainstream is leveled by those environmentalists and ecological economists who profess an ecological or a steady-state worldview. The latter implies that energy/material flows through the economy should be maintained at a nongrowing optimum, safely within the means of nature. These analysts see the present economy not as a separate system, but rather as an inextricably integrated, completely contained, and wholly dependent

growing subsystem of a dynamic but nongrowing ecosphere (e.g., [Daly, 1991](#)). From this perspective, the economy (i.e., the human enterprise) is potentially parasitic on nature. Hence, people must be considered not only as economic agents but also as potentially destructive ecological agents.

Indeed, the ecological perspective actually sees the so-called environmental crisis as a human ecobehavioral crisis. This is a critical distinction. The former term externalizes the problem, effectively blaming it on a defective environment, which then needs to be fixed. By contrast, the latter term traces the problem to its source – the nature and behavior of people themselves – and suggests that it is the latter that need fixing. As we shall see, this is the starting point for EFA.

Human Ecology/Economy and the Second Law

If humans are ecological entities, then human activity is governed by natural laws. In particular, economic production requires continuous, irreversible energy and material transformations, and these transformations are ultimately governed by the second law of thermodynamics. This fundamental law is ignored by conventional economic models.

In its simplest form, the second law states that with every spontaneous change, an isolated system will tend toward equilibrium; alternately, the entropy of isolated systems always increases. Available energy dissipates, concentrations disperse, and gradients disappear. An isolated system thus becomes increasingly randomized in an inexorable slide toward thermodynamic equilibrium. This is a state of maximum entropy in which there is no structure and nothing can happen.

The second law was originally formulated for simple isolated systems close to equilibrium. However, even complex open systems are subject to the forces of entropic decay. Any differentiated far-from-equilibrium system has a natural tendency to erode and unravel.

But not all complex systems disintegrate in this way. Many biophysical systems, from individual fetuses to the entire ecosphere, actually gain in organizational complexity and mass over time (i.e., they increase their distance from equilibrium). This seemingly paradoxical behavior can readily be reconciled with the second law. Biophysical systems exist in loose, nested hierarchies, each component system being contained by the next level up and itself comprising a chain of linked subsystems at lower levels. Living systems can therefore import available energy and material (negentropy) from their host environments and use it to maintain their internal integrity against entropic decay and to grow ([Kay and Regier, 2000](#)). They also export the resultant waste (entropy) back into their hosts. In effect, modern formulations of the second law posit that all highly ordered systems grow and develop (increase their internal order) at the cost of destroying order at higher levels in the systems hierarchy ([Schneider and Kay, 1995](#)). Because such systems maintain themselves by continuously degrading and dissipating available energy and matter, they are called “dissipative structures” ([Prigogine, 1997](#)).

Now, the human enterprise is clearly one such highly ordered, complex, dissipative structure. Both our biological and our industrial metabolisms require enormous inputs of

high-grade energy and material resources from the rest of the ecosphere for their maintenance and growth. Indeed, from the ecological perspective, humans are strictly secondary producers – all production by the human enterprise, from the increase in population to the accumulation of manufactured capital, requires the consumption of a much larger quantity of energy and material first produced by nature (we can sometimes increase the amount of incoming solar energy captured by photosynthesis through irrigation or by building terraces for agriculture).

Moreover, recall that within the global hierarchy, the economy is a dependent subsystem of the ecosphere. In effect, the expanding human enterprise is positioned to consume the ecosphere from within. Beyond certain limits, continuous population and material economic growth is, therefore, inherently self-destructive. This reality suggests a necessary second law condition for sustainability: material consumption and waste production by the economy must be no greater than the resource production and waste assimilation capacity of the ecosphere.

Homo Sapiens: The Archetypal Patch Disturbance Species

Evidence to support the ecological view has accumulated throughout history. Even preagricultural humans had significant effects on local ecosystems’ structure and function and on the biodiversity of their habitats. This was the inevitable consequence of the second law combined with two additional facts of human biology: human beings are large animals with correspondingly large individual energy and material requirements (i.e., we are huge consumers) and humans are social beings who live in extended groups. Consequently, whenever human hunter-gatherers invaded a previously stable ecosystem, their material demands would significantly alter established energy and material pathways, benefiting some nonhuman species and harming others. People invariably perturb or disturb the systems of which they are a part.

Perhaps the most dramatic evidence is the permanent systemic changes that occur when humans first invade and settle a new habitat. Consider biodiversity loss. The recent paleo ecological, anthropological, and archeological literature tells a convincing story of the extinctions of large mammals and birds that accompanied first contact and settlement of their habitats by human beings ([Diamond, 1992](#); [Flannery, 1994](#); [Ponting, 1991](#)). It seems that everywhere on earth that paleontologists have studied and that humans first reached within the past 50 ky, human arrival approximately coincided with massive prehistoric extinctions. In North America, South America, and Australia, about 72%, 80%, and 86%, respectively, of large mammal genera ultimately became extinct after human arrival. Scientists estimate that with only Stone Age technology, the Polynesians exterminated more than 2000 bird species, about 15% of the world total.

All this is to emphasize that humans are, by nature, a patch-disturbance species, a distinction we share with other large mammals ranging from beavers to elephants. Large animals, due to their size, longevity, and food and habitat requirements, tend to have substantial physical and systemic

impacts on the ecosystems that sustain them. A patch-disturbance species may thus be defined as any organism that, usually by foraging, degrades a small central place greatly and disturbs a much larger area away from the central core to a lesser extent.

There is, of course, a major difference between human patch disturbance and that of other species. Because human knowledge and technology are uniquely cumulative, human patch disturbance has been intensifying since the Neolithic. It received a major boost with agriculture and became the dominant force in the ecosphere with the use of fossil fuels and the industrial revolution. (Cheap, plentiful fossil fuels have enabled humans to accelerate the exploitation of everything else.) Today, human patch disturbance is evident on a global scale in the form of such persistent negative trends as greenhouse gas accumulation, increasing climatic variability, ozone depletion, tropical deforestation, desertification, ocean acidification, and accelerating biodiversity loss. Ultimately, the erosion of systems integrity may lead to the irreversible loss of basic life support functions.

Whatever joy one might take from the human symphony, the fact that material economic growth now threatens critical biophysical systems sounds a discordant note. Global change implies that economic activity is pressing against the limits of human carrying capacity at the expense of other species – and ultimately of people themselves. Regrettably, the concept of human carrying capacity has long been rejected by mainstream analysts, but for reasons explained below, it is the organizing principle of ecological footprinting.

Revisiting Human Carrying Capacity: The Roots of Ecofootprint Analysis

Ecologists who study nonhuman species generally define carrying capacity in terms of the average number per unit area of deer, elk, or other species that a particular habitat can support indefinitely (i.e., without permanent deterioration). However, because of such factors as climatic variability and community succession, instantaneous carrying capacity is constantly changing. Carrying capacity is therefore not a particularly rigorous concept, even when applied to nonhuman species with simple stable demands on their ecosystems. It is all the more problematic when applied to humans, whose demands on the environment are anything but simple and stable.

Indeed, many economists and other cornucopians argue that interregional trade alone is virtually enough to cancel concerns about human carrying capacity. Any region or country that can trade services or surpluses of resource A for needed supplies of resource B need not be limited in numbers or economic growth by the theoretical carrying capacity of its home territory. Furthermore, if trade fails, we can always rely on human ingenuity and technology to increase carrying capacity. These are seemingly powerful arguments, and they explain how such densely populated countries as the Netherlands and the UK can remain economically vigorous despite having long exceeded their domestic carrying capacities.

But let us examine the assumptions here. The idea that trade acts to increase local carrying capacity treats each trading region as an isolated open system. Looked at in the aggregate, the situation is cloudier. The world as a whole is a materially closed system. Resources imported to and consumed in region A are no longer available for consumption in the exporting region B and vice versa. Hence, the exchange may result in a one-time increase in the population of each region taken separately, but it also increases global consumption and total pollution, and may deplete local stocks of natural capital, thereby limiting future options. Thus, although the total human load increases, there is no unambiguous increase in total load-bearing capacity.

Indeed, under some circumstances, unfettered trade can lead to a permanent loss of carrying capacity. Global trade exposes pockets of scarce resources everywhere to the largest possible market. This subjects them to ever-greater exploitation pressure, often to the point of depletion or collapse. (Such is the history of trade in fisheries products, e.g.) In short, instead of increasing load-bearing capacity, trade just shuffles it around, increasing local populations, resource depletion, and ecosystems degradation. This ensures that all countries, their economies happily expanding through trade, hit the (now shrinking) limits to growth simultaneously. People everywhere will suffer the consequences of significant climate change, for example.

What about human ingenuity? The general argument here is that cumulative knowledge and technological skills enable humans to squeeze more out of the environment than nature-in-the-raw can provide. This is achieved mainly by continuously increasing resource productivity and by creating substitutes for any resources that are eventually depleted. In these ways, we are able to increase the capacity of any given habitat to support humans and their activities without practical limit.

Let us take these points one at a time. The so-called green revolution, for example, is frequently cited as a miracle of human technological prowess. High-input fossil-fuel-dependent production agriculture has, in fact, greatly increased the short-term productivity (and carrying capacity) of arable land. This seemingly banished the threat of Malthusian famine and certainly facilitated the modern population explosion. However, this miracle was achieved largely by supplementing renewable sun, soil, and rain with nonrenewable fossil fuel, fertilizer, pesticides, and depletable groundwater at a great cost of soil degradation, biodiversity loss, widespread pollution, and falling water tables. The net effect is a swollen human population, likely in overshoot, and increasingly dependent for survival on nonrenewable artificial inputs, even as pollution mounts and natural long-term load-bearing capacity is steadily eroded. The peaking of conventional oil production, diminishing returns to fertilizer, growing water shortages, and globally rising food prices all suggest that we may be entering an era of global food insecurity.

Another vaunted potential fix is our demonstrated ability to greatly increase resource productivity, to do more with less. In theory, more efficient technologies should enable a constant energy and material supply to support a given population at a higher material standard, or a higher population at the same material standard, thereby seeming to increase carrying capacity.

Unfortunately, real-world practice has so far betrayed theoretical promise. The steady gains in material efficiency in the post World War II period have been accompanied by both an exploding population and increasing consumption. In a study of material flows in a selection of the world's most technologically advanced and efficient countries, the World Resources Institute (WRI) showed that, although technology and economic restructuring have substantially weakened the link between economic growth and resource throughput since 1975, there has also been a gradual increase in per capita natural resource use. The study therefore concludes that actual dematerialization has not been achieved (WRI, 2000, p. 19). In fact, efficiency gains may actually work against conservation by lowering prices and raising incomes. This gives people more money to spend on cheaper goods and services so that total throughput – human load – keeps expanding. Also, note that the WRI analysis says nothing about the explosive increase in per capita consumption in developing countries, where most future population and material growth is expected to occur.

Finally, overconfidence in resource substitution is also problematic. It is true that human ingenuity has been markedly successful at finding replacements for simple material inputs to production. For example, optical fiber is as much a product of mind as of nature and has displaced much of the demand for copper wire. However, as ecological economist Daly (1991) has emphasized, there are many more circumstances under which technology and nature are complements, not substitutes. More fish boats cannot for long substitute for fewer fish; more saws and carpenters are no substitute for less lumber. Indeed, the primary products of natural capital (e.g., lumber, steel, aluminum) are actually prerequisites for manufactured capital (e.g., a fish boat) since the latter is made from the former. More generally, we should emphasize that the growing need for technology-based substitutes (e.g., fertilizer) is a warning signal that natural load-bearing factors (e.g., productive soil) are being permanently eroded.

In summary, confidence that expanding trade and technical wizardry have infinitely expanded human carrying capacity and banished the Malthusian specter forever is premature. Carrying capacity is still very much applicable to humans, and given present trends, it is likely to become a major preoccupation of global development policy in the coming decades. However, as this paper shows, we need new approaches to the analysis of carrying capacity, methods that account for uniquely human cultural attributes, including trade and technology.

The Logic and Structure of Ecological Footprint Analysis

Basic Concepts

EFA is one such analytic method. Ecofootprinting starts from the premise that, conscious of it or not, modern human beings are integral components of the ecosystems that support them and are therefore still very much dependent on ecosystem integrity and the land (Rees, 1996; Wackernagel and Rees, 1996).

The method also explicitly recognizes (1) that whether one consumes locally produced products or trade goods, the land connection remains intact, however far removed from the point of consumption some of that land may be, and (2) that no matter how sophisticated our technology, the production/consumption process requires some land- and water-based ecosystems services. Ecofootprint analysis thus incorporates the trade and technology factors simply by inverting the standard carrying capacity ratio: rather than asking what population can be supported by a given area, ecofootprinting estimates how much productive area is needed to support a given population, regardless of the location of the land or the state of technology.

Ecofootprinting builds on traditional trophic ecology by constructing what is, in effect, an elaborate foodweb for the study population. This requires quantifying the material and energy flows supporting the population using production and trade data obtained from national statistical agencies and such international data sources as the Food and Agriculture Organization's Corporate Statistical Database (FAOSTAT). Of course, the human foodweb differs significantly from those of other species. In addition to the material and energy required to satisfy our biological metabolism, a human foodweb must also account for the needs of humanity's industrial metabolism.

Ecofootprinting is further based on the fact that many material and energy flows (resource consumption and waste production) can be converted into a corresponding area of productive land and water ecosystems. Summed up, the total area represents the biocapacity needed to produce the biophysical goods and services used by the study population. Thus, the EF of a specified population is the area of productive land and water ecosystems that the population requires, on a continuous basis, to produce the resources it consumes and to assimilate the wastes it produces, wherever on earth the relevant land/water may be located. A complete ecofootprint analysis would therefore include the population's domestic ecosystem requirements, plus the area it appropriates through net commodity trade, plus its demands on the global common pool for free land- and water-based services (e.g., the carbon sink function).

The area of a given population's ecofootprint depends on four factors: the size of the population, the people's average material standard of living, the productivity of the land/water base, and the technological efficiency of resource harvesting, processing, and use. Regardless of how these factors interact, a population's ecofootprint represents much of its global demand on biocapacity, including ecosystems located half a planet away. We can therefore think of the EF as the globally extended habitat patch ecologically occupied by the study population.

It is critical to recognize that ecofootprints represent ecologically exclusive areas. The productive capacity used by one human population is not available for use by another. Although two or more human groups may share in the output of the same exporting region, the total ecosystem area appropriated is the sum of the areas required by the individual populations. In the final analysis, all human populations are in competition for the available load-bearing capacity of the earth.

The Method in Brief

EF estimates are conceptually simple but data rich. Population EFs are generally based on the final demand for goods and materially intensive services by the referent population. Thus, the first step in calculating the EF of a study population is to compile the total annualized consumption of each significant commodity or consumer good used by that population.

For accuracy, consumption data should be trade-corrected. Thus, the population's consumption of wheat can be represented as follows:

$$\text{domestic consumption}_{\text{wheat}} = \text{domestic production}_{\text{wheat}} + \text{imports}_{\text{wheat}} - \text{exports}_{\text{wheat}}$$

The second step is to convert the consumption of each item into the land area required to produce that item by dividing the total consumption by land productivity or yield. This actually gives us the EF of the individual item. In general: $a_i = c_i/\gamma_i$ where: a_i is the ecofootprint of item i in hectares, c_i is the total consumption of item i in kilograms, and γ_i is the yield of item i in kilograms per hectare. Thus, for wheat:

$$a_{\text{wheat}} = c_{\text{wheat}}/\gamma_{\text{wheat}} = \text{kg}_{\text{wheat}}/(\text{kg}_{\text{wheat}} \times \text{ha}_{\text{wheat}}^{-1})$$

Next, the aggregate EF of the population, (F_p), is determined by summing the footprints for the n individual items:

$$F_p = \sum_{i=1}^n a_i$$

Finally, the per capita EF, f_c , is obtained by dividing the total population footprint by population size, N :

$$f_c = F_p/N$$

For some wastes (such as carbon dioxide emissions) or nutrients (such as phosphates and nitrates), it is also possible to calculate the land (or aquatic) ecosystem area required for sustainable assimilation and recycling. In these cases, the assimilation rate per hectare and year is substituted for γ (yield) noted earlier. Most published ecofootprint estimates include an estimate of the carbon sink that would be necessary to assimilate the population's carbon dioxide emissions (but this does not imply an adequate supply of assimilative ecosystems).

Ecofootprint analysts avoid double-counting whenever possible. For example, some consumer products such as leather goods are the byproduct of another industry (such as beef production). In such cases, one would generally count only the primary land requirements (the grazing and grain lands required for feeding cattle). For some purposes, of course, it may be of interest to apportion the estimated ecofootprint among the various products associated with the primary use.

In general, we err on the side of caution in making EF estimates. For example, if there is dispute over, or several estimates of, land productivity, we use the higher estimate (this reduces footprint size). Most EF and biocapacity calculations are therefore likely to under rather than overestimate. **Box 1** describes a common elaboration of basic EFA that involves conversion of primary ecofootprint estimates into their equivalent in hectares of global average productivity (gha). This step simplifies data management and facilitates international comparisons.

Human Ecological Footprints: Implications for Global Sustainability

So, how big are our EFs? Most citizens of industrialized high-income countries feel so distanced from nature that it has

Box 1

In practice, population ecofootprints and biocapacities are usually estimated in terms of global hectares (gha of hectares of world average productivity). In converting ecosystem areas to gha, analysts use yield factors to reflect national differences in land productivity and equivalence factors to account for differences among ecosystem types. For example, if Country A's cropland is twice as productive as world average cropland, and world average cropland is twice as productive as world average landtypes, then 1 ha of A's cropland is the equivalent of 4 gha. Conversely, if country A has an estimated per capita cropland ecofootprint of 2 gha, this is equivalent to just 0.5 actual ha of A's domestic biocapacity.

Converting national consumption data to gha simplifies EF estimates because we do not have to identify the sources of trade goods or locations of waste sinks, or determine the productivity and assimilative capacities of the corresponding production/assimilation areas. As important, using a common base yield facilitates comparison among countries and comparisons of individual countries with the global total EF. Using gha is also increasingly realistic for many countries that are heavily dependent on trade flows of commodities from various sources. (Note that the world population ecofootprint estimate in gha would be the same as the global estimate based on actual yields and ecosystem types.)

For some kinds of analyses, of course, it might be necessary or useful to base the EF calculation on actual land/water yields where sources are known and data are available (e.g., see [Kissinger and Rees, 2010](#)). Also, to compare a country's or a region's estimated EF in gha with its domestic biocapacity (i.e., to determine that country's ecological deficit or surplus), we must know the actual productivity of various domestic land categories (cropland, pasture land, forests, carbon sinks, etc.).

For example, assume that we want to know whether a given country is potentially food self-sufficient. If that country's cropland is twice as productive as world average cropland, we would multiply the area of its cropland by a yield factor of two before comparing it with (i.e., subtracting it from) its estimated cropland footprint in gha. Note, however, that if the higher productivity of domestic land is the result of intensive fertilizer and pesticide use, any apparent reduction in the ecological deficit due to higher cropland productivity will be at least partially canceled out by the increase in the ecological footprint attributable to the use of agricultural chemicals (fossil fuels are an important feed-stock in the manufacture of these inputs).

At present, the Global Footprint Network estimates both the ecological footprint (demand on ecosystems) and the biocapacity (domestic supply or ability to meet demand) of more than 200 countries and territories. The results, updated annually, use greater than 5000 data points for each country, each year, derived primarily from national statistical accounts and internationally recognized sources such as the United Nations' Food and Agriculture Organization, the International Energy Agency, the UN Statistics Division, and the Intergovernmental Panel on Climate Change. Details of the current methods and results are available from [WWF \(2008\)](#), [WWF \(2010\)](#), and on-line from the Global Footprint Network by following the links at <http://www.footprintnetwork.org> [Lubchenco, 1998](#).

simply never occurred to them to ask, “How much of the earth’s surface is dedicated to supporting just me in the style to which I have become accustomed?” They are generally shocked to learn that average residents of the United Arab Emirates, North America, Australia, Europe, Japan, and other rich countries require the biophysical output of 4–10 gha (10–25 acres) of biophysically productive land and water each to support their consumer lifestyles (Wackernagel *et al.*, 1999; WWF, 2008, 2010). Such large ecofootprints are also sported by members of wealthy urban elites throughout the developing world. Consider these data in light of the fact that there are only 1.8 gha of productive land and water ecosystems per capita (biocapacity) on Earth.

The Functional Footprints of Cities

These findings should alter our perceptions about many things. To begin, they should change how we think about cities and urban land. Over 40 years ago, American ecologist Eugene Odum wrote, “Great cities are planned and grow without any regard for the fact that they are parasites on the countryside which must somehow supply food, water, air, and degrade huge quantities of waste” (Odum, 1971). Ecofootprinting enables us to quantify the extent of this urban parasitism. For example, in 2006, Canada’s largest city, Toronto, had a population of approximately 2,503,281 living in an area of 630 km². Assuming they are typical Canadians, Toronto’s citizens had an average EF of about 7.4 gha (18 acres). Thus, the EF of Toronto was 185,243 km² or about 294 times the size of its political area. Clearly, most of the city’s supportive ecosystems are located at a great distance from the people they sustain; indeed, they are scattered all over the planet.

This situation is characteristic of high-income cities. In a particularly comprehensive analysis, Folke *et al.* (1997) estimated that the 29 largest cities of Baltic Europe appropriate for their resource consumption and waste assimilation an area of forest, agricultural, marine, and wetland ecosystems 565–1130 times larger than the areas of the cities themselves. A study for the International Institute for Economy and Development in London shows that the ecological demands of that city alone appropriate an area scattered around the world equivalent to the entire biocapacity of the UK.

Such findings have important implications for both urban development and rural sustainability in the twenty-first century. Some analysts interpret the global migration of people from rural areas to the city as implying that modern humans are abandoning the countryside and becoming less dependent on the land. This is an illusion. The reality is that productive croplands, pasture lands, and forests everywhere are being used more intensely than ever to sustain the world’s burgeoning urban populations. The human occupants of cities may think of the latter as their principal habitat, but cities per se represent only a tiny fraction of the total increasingly urban-centered human ecosystem.

There is, of course, a certain mutualism between the city and the countryside. Cities need the resources of rural areas and rural areas benefit from urban markets and technology transfers from cities. However, while rural areas could survive without cities, the dependence of cities on rural environments

is absolute. In short, there can be no urban sustainability without rural sustainability. In this light, we might even want to reconsider what we think of as urban land – in a whole-systems ecological sense, the great plains of North America, one of the world’s major breadbaskets, are an essential component of the increasingly urban global human ecosystem.

According to United Nations’ projections, there will be 27 cities with populations exceeding 10 million by 2015 (up from only 1 in 1950). Forty-four more cities will have populations of 5–10 million by the same year. This should trigger at least a cautionary alarm. The world’s megacities – all cities for that matter – are dependent on a vastly larger area of productive lands outside their boundaries and political control. But just how secure can any urban population be if the lands represented by its ecofootprint are under threat from climate change or the population’s access to essential biocapacity is denied by resource scarcity (think peak oil) or geopolitical turmoil?

Ecofootprints, Global Development, and Social Equity

It is not just cities that overshoot the productive capacity of ecosystems within their political domain. As a result of continuous population growth, rising material demand, globalization and expanding trade, most high-income countries have an ecofootprint several times larger than their domestic biocapacities. In effect, they are running massive ecological deficits with the rest of the world. The EFs of wealthy consumers in particular now roam all over the planet.

Ominously, ecofootprint studies suggest that humanity is now running a global ecological deficit of up to 50% and is accumulating a nonrepayable ecological debt. The global average ecofootprint is 2.7 gha compared with only 1.8 gha per capita of available biocapacity (WWF, 2010). (We can refer to this 1.8 gha as the per capita equitable or fair Earth-share, each person’s equal allocation of global biocapacity.) Thus, even at current average levels of economic production and consumption, the human load already exceeds the long-term carrying capacity of the earth – the world’s population is living, in part, by depleting essential natural capital and overcharging vital waste sinks. The direct empirical evidence (e.g., climate change, ocean dead zones, tropical deforestation, fisheries collapses) is the stuff of daily headlines.

This means that contrary to the assumptions of prevailing international development models, the so-called first world material lifestyles are not sustainably extendible to the entire world population using prevailing technology. Wealthy consumers, who, on average, require the goods and life support services of 4–10 gha of productive ecosystems to support their consumer life-styles, use greater than two- to five- times their equitable share of global biocapacity. Meanwhile, the great majority of humankind is understandably not satisfied with its present material lot and is determined to improve it. (Despite the industrial revolution in China, in 2007, the EF of the average Chinese was only about 2.2 gha and Bangladeshis were getting by on only 0.6 gha.) The problem is that to support all seven billion members of the human family at the average North American material standard would require over three additional Earth-like planets (and this does not account

for the needs of the two billion or more people to come by the middle of the century).

If we are at or beyond the human load-bearing capacity of the planet, then the only way additional population or material growth can be sustained, without ravaging biodiversity and ultimately destroying the ecological basis of human life, is through massive cutbacks in resource consumption by the presently wealthy. North Americans, for example, should be planning to reduce their EFs by about 80%. This is necessary to vacate the ecological space necessary for justifiable growth in low-income countries. In theory, such cuts could be achieved while actually increasing life quality through a tightly managed new efficiency revolution in rich countries (doing much more with less) combined with an absolute reduction in material demand (i.e., a shift to simpler but more satisfying lifestyles).

Other carrying capacity studies have reached similar conclusions. Using data on current waste discharge rates and the assimilative capacity of biophysical systems, the Sustainable Europe Campaign has estimated that sustainability requires an approximately 50% reduction in the material throughput of the global economy in the coming decades. However, equity considerations demand that developed countries reduce their consumption of various nonrenewable resources by between 88% and 94% (Carley and Spapens, 1999).

These might seem to be extreme conclusions and impossible goals. However, the United Nations Environment Program's *Global Environment Outlook 2000* report also argues the need for a 10-fold reduction in resource consumption by high-income countries. Even the Geneva-based world Business Council for Sustainable Development acknowledged as early as 1993 that "industrialized world reductions in material throughput, energy use, and environmental degradation of greater than 90% will be required by 2040 to meet the needs of a growing world population fairly within the planet's ecological means" (BCSD, 1993).

If so-called postindustrial society fails to meet this challenge, the anticipated doubling and doubling again of human material demand in the next half-century will be disastrous for sustainability. It will certainly negate most present conservation efforts. As explained next, the expanding human EF inevitably reduces the ecological space available for other species.

Human Ecological Footprints and the Biodiversity Crisis

Human beings are uniquely successful among large mammals in mastering the variety of environments on earth and in expanding both numerically and spatially over the globe. Our capacity to extend our aggregate ecofootprint continuously is attributable to several species-specific qualities, of which perhaps three stand out.

First, humans have a remarkably variable diet – we have wide-ranging omnivorous tastes and if we cannot consume something directly (such as grass), we domesticate an animal that will and then consume the animal or its products such as milk. This means that humans may well possess the broadest food niche of any vertebrate on the planet. Second, humans

are as behaviorally adaptable as they are catholic in their diets. Together, these two factors make virtually any terrestrial ecosystem on earth accessible to *Homo sapiens*. No other species has managed successfully to colonize and dominate virtually all major terrestrial ecosystem types, from grasslands and forests to deserts and tundra, on all the world's significant land masses. Finally, we are creatures of language, culture, and cumulative learning. Technological advances have enabled humans relentlessly to increase the intensity of resource exploitation and to extend their ecofootprint into virtually all remaining productive habitats on the planet. For example, thanks to electronic fish-finding devices and ruthlessly effective fishing gear, humans have also become the functionally dominant marine mammal. By the mid-1990s, the world's fishers were appropriating the equivalent of 25–35% of the product of net photosynthesis from the 10% of the oceans that produces 96% of the catchable fish.

We previously noted that human ascendance has historically been achieved at the expense of other species. People's material demands, culminating in today's global consumer society, have steadily appropriated an increasingly disproportionate share of the planet's finite productive and sink capacities. The recent human dominance of ocean ecosystems provides several examples of the resulting biodiversity loss.

Certain modern fish-harvesting techniques have devastating impacts on the physical and biological structure of marine habitats, thereby reducing the productivity, diversity, and abundance of both target and nontarget species. Various surveys reveal that fishers now drag heavy trawls over all the oceans' continental shelves at least once every two years and some areas are hit several times in a season. In heavily fished regions of the North Sea, trawlers make up to seven passes annually with nets and chains weighing up to five tons. The total area affected by trawls is 150 times larger than the area of forest clear cut globally each year.

Many fish-stock depletions and the destruction of benthic communities are the direct result of the increasing intensity of commercial fishing. However, other systemic problems stem from the fact that expanding the human marine ecofootprint inevitably diverts an ever greater proportion of the finite energy budget of the sea away from other marine predators, including various fish, birds, and mammals.

A particularly interesting, if still somewhat speculative example of the resultant domino effect, begins with the depletion by human predation of fin and sperm whales in the North Pacific Ocean and southern Bering Sea during the post World War II period through the 1980s (Estes *et al.*, 2004). The weight of evidence suggests that the decline of whale stocks forced mammal-eating orcas (killer whales) to shift a significant part of their diet to pinnipeds – Steller's sea lions and harbor seals. The populations of these mammals in the Aleutian Archipelago declined drastically during the 1970s and 1980s and had been reduced to 10–20% of their former abundance by the 1990s. With the decline of sea lions and seals, the orcas turned to eating sea otters – smaller, less fatty animals – whose populations also declined by 80% during the 1990s.

But the systemic shifts and biodiversity losses do not end there. Sea otters are a keystone species in the shallow marine kelp forests that constitute their preferred habitat. Among the

otters' major prey are sea urchins, which, in turn, graze on kelp. As the otter population declined, there was an explosion of sea urchins, leading to the destruction of the kelp beds by overgrazing. So it is that human overharvesting of whales seems to have precipitated the collapse of one of the most productive inshore-marine ecosystems in the North Pacific, as so-called sea urchin barrens spread along the Aleutian Island chain and the adjacent coast of Alaska. (Dramatic as this example might seem, it is only the final chapter of a longer book. Direct human overharvesting of sea otters for their pelts, beginning in the nineteenth century, had long since ravaged the more southern kelp forests that previously characterized much of the Pacific coast of North America from California north.)

Some popular accounts of this phenomenon have emphasized the role of orcas in switching prey from pinnipeds to sea otters. Certainly, this was an important link in the chain of events, but the most interesting structural change leading to the collapse of the near-shore ecosystem was the human displacement of orcas from their role as the top carnivores in the offshore ecosystem. As human predation on whales forced orcas from their historic place in the foodweb, they were forced to switch to seals and, finally, sea otters (a much inferior food source).

This example underscores how, conscious of it or not, *Homo sapiens* has become the ecologically dominant marine mammal. But the main point to take away is that uncontrolled increases in human appropriations of bioproductivity inevitably result in the rerouting of energy and material flows through the affected ecosystems – marine or terrestrial – with consequent and potentially permanent changes in ecosystem structure and function.

We now recognize that several mechanisms are at work as humans extend their ecofootprints. People:

1. Passively displace other species from their food niches or appropriate their habitats. (Human predation on whales restructured the ecosystems of the northwest Alaska coast; agriculture replaced bison and many other species on the Great Plains of North America; clearing for crops and grazing has destroyed thousands of species in former tropical forests.)
2. Actively eliminate nonhuman competitors – other species that compete with us for our food. (We shoot wolves that hunt ungulates and seals that eat commercially valuable fish; we poison insects that would devour our crops.)
3. Deplete both self-producing and nonrenewable natural capital stocks. (Humans overexploit many wild prey populations from rhinos and tigers to fish; destroy whole ecosystems such as forests; and deplete vital assets such as groundwater, soils, and fossil fuels.)

These processes are all consumption related. The first two are forms of competitive exclusion. Technological man is simply more effective than other organisms at appropriating nature's bounty for our own use. Because energy and material flows used by people are irreversibly unavailable for other species, the latter decline, even to extinction, at least locally.

The third mechanism, stock depletion, is the product of many things, including blind ignorance, material greed, confidence in technological substitution, sheer desperation,

and the relentless working of the so-called common property problem on an overcrowded planet. Sometimes, it is even the result of willful disregard on the part of those who give no moral standing to other creatures or who simply do not care about the state or the fate of the world.

Economic globalization, the sanctioning of greed, the rise of consumerism, and the spread of energy-intensive technologies have intensified all these processes. Overharvesting and habitat destruction are driving what some analysts refer to as "the sixth extinction." According to Biologist Wilson, the earth is now experiencing the greatest extinction episode since the natural catastrophes at the end of the Paleozoic and Mesozoic eras. The current species extirpation rate is 100–1000 times prehuman levels inferred from the fossil and paleontological record. A quarter of bird species have already been extinguished by people and fully a quarter of the 4400 mammal species living today are on a path of decline that, if not reversed, is also likely to end in extinction.

The contemporary human ecofootprint is also characterized by massive increases in waste production. Not surprisingly, the resultant pollution is adding to the toll on biodiversity. A poignant example is the phenomenon of "coral bleaching" which has been in the news since the mid-1980s. This effect is produced when the animal component of coral organisms – corals are a mutualistic union of animal polyps and plant (algae) cells – expel their algal cohabitants as a result of thermal or other stress. The loss of algae leaves the coral pale, washed out (bleached), and unable to grow or reproduce. In the exceptionally warm spring and summer of 1998, coral bleaching associated with a 1 °C increase in ocean temperature extended across the tropics, including, for the first time, the Indian Ocean. Reports indicate that 70–90% of corals in the Indian Ocean basin were affected. By 2004, approximately 20% of the world's coral reefs had been destroyed by bleaching and other human impacts and showed no sign of recovery.

Some scientists have referred to the bleaching and die-back of corals as an unprecedented ecological disaster. Coral reefs are among the most diverse and productive ecosystems on the planet. Numerous fisheries, particularly locally important food fisheries, and millions of people are sustained, in part, by the productivity of corals. What economic and social costs would be incurred if the decline of corals and associated reef habitats continues unabated? How will we measure the ultimate consequences of the sheer loss of biodiversity? Most importantly, what does the apparent spread of the problem indicate about the state of the ecosphere in general and the marine environment in particular?

These are important questions, but the main point is that to the extent that coral bleaching is caused by human-induced global warming, it is the indirect result of greenhouse gas accumulation in the atmosphere. (The earth's carbon sinks are overflowing.) The attendant biodiversity loss is therefore the distal product of the industrial world's addictive dependence on fossil fuels and our ever-expanding industrial metabolism. Regrettably, because of lag effects and the sheer inertia of the climate system, the world is committed to additional climate change/global warming for decades to come, even if significant mitigative actions were to be taken today. Certainly, coral bleaching will not be reversed by any

political action feasible under the prevailing global development model.

All these examples underscore the inverse relationship between growth of the human ecofootprint and biodiversity (the competitive exclusion principle at work). Unfortunately, at present, ecofootprint analysis does not directly track biodiversity losses. However, the negative correlation is most directly associated with the conversion of wildlands to agriculture, intensive (including plantation) forestry, and various forms of habitat fragmentation. Many of these conversions are measurable. It may therefore eventually be possible, using the historical record and principles of biogeography, to link some index of biodiversity loss to the growth of population ecofootprints.

Whether or not this relationship can be rigorously defined, the basic point stands. To the extent that further human population and material growth requires the clearing of forests and the intensification of agriculture, and is accompanied by urban sprawl and pollution, it necessarily means less ecological space to sustain nonhuman species and ecosystems. Biodiversity loss is thus virtually certain to accelerate with anticipated growth of the human enterprise.

Assessing the Ecological Footprint Approach

Conceptual and Methodological Strengths

Ecofootprint analysis brings several methodological strengths to bear in assessing the state of the world. First, it is compatible with various concepts developed by other analysts to address human ecological problems. For example, the EF concept

- incorporates and extends George Borgstrom's 1960s notion of "ghost acreage," referring to the extraterritorial food lands required to support densely populated regions and countries.
- corresponds closely to Paul Ehrlich's and John Holdren's 1970s definition of human impact on the environment: $I = PAT$, where I is impact, P is population, A is affluence, and T is technology. The population EF (F_p) corresponds to impact (I) in the Ehrlich–Holdren formulation and is a function of population size (P) and consumption (C). However, because consumption is a function of income (A) and the state of technology (T), I , like F_p , is also a function of population and consumption. Thus, F_p is an area-based analog of I .
- provides one measure of human load defined by Catton (1980) as a function of population size and average individual impact (consumption again). The larger the footprint, the greater the load. (Catton defined carrying capacity as the "maximum persistently sustainable load.")
- is conceptually related to the embodied energy (emergy) analyses of ecologist Howard Odum and recognizes the importance of the second law of thermodynamics to human affairs as stressed by ecological economists Nicholas Georgescu-Roegen and Herman Daly. Indeed, the area represented by the EF can be conceived as the photosynthetic surface (solar collector) needed to replace

the free energy (essergy or negentropy) continuously being dissipated by humans and their industrial metabolism.

However, for all its technical compatibility, perhaps the major strength of ecofootprint analysis is conceptual simplicity and intuitive appeal. First, the "footprint" metaphor seems particularly effective in communicating the idea that we each have an impact on the Earth for which we are responsible through consumption choices. Second, ecofootprinting consolidates real data on a variety of energy and material flows into a single concrete variable, land area. Land is a particularly powerful indicator because it too is readily understood by ordinary people.

Because the supply of land is finite at any scale, ecofootprint analysis provides a measure of human demand (load) for comparison with supply (load bearing capacity) at all geographic levels from local to global. (The ability to compare supply and demand is a major strength of EF analysis shared by few other sustainability indicators.) Such comparisons suggest several secondary indices of (un)sustainability that can be used to stimulate discussion of sustainability options or in establishing measurable policy targets. For example, if we are running a local or a regional ecological deficit, the question becomes: is this a major problem and, if so, what must be done to reduce it? In an era of increasingly ecological and potential geopolitical uncertainty, is it wise for any region or nation to become significantly dependent on distant sources of supply for critical resources? Does a growing ecological deficit suggest that a region or a nation should develop policies to become more self-reliant, by, for example, investing in conservation or restoration of vital natural capital such as arable soils? What does a growing deficit imply for population policy?

Note that national ecodeficits may ultimately prove to be more important than fiscal deficits and yet they are totally ignored in most national accounting systems. Moreover, what about humanity's total ecological deficit that constitutes the global sustainability gap?

Methodological Limitations and Other Criticisms

Although it has considerable conceptual and operational strength, ecofootprint analysis has attracted its share of brickbats and objections. Some criticisms stem from real weaknesses of the method or from misunderstandings of its scope and potential. Others, however, seem more to reflect the critic's discomfort with the findings and implications of EFA than they do flaws in the method. Some of the methodological limitations and common critiques are as follows:

The Question of Scope

Some critics have argued that the term EF is misleading because the method does not capture the full range of ecologically significant impacts on the ecosphere.

It is quite true that ecofootprint calculations are not all-encompassing. They do not account for many pollution effects such as ozone depletion or endocrine (hormone) mimicry, to cite just two examples. Ecofootprinting was designed and is best suited for those human load factors that are readily convertible into a land or water ecosystem equivalent. In fact,

estimates do not even tell the whole land and water story. Various minor consumption categories are yet to be included and analysts are only beginning to examine the spatial implications of waste discharges other than carbon dioxide and essential nutrients.

To be sure, it is unlikely that ecofootprint analysis will ever cope satisfactorily with various toxic waste discharges into the ambient environment. The biological effects of chronic low-level chemical contamination (e.g., carcinogens), for example, do not readily translate into functional land area. However, this may not be as problematic as it seems. Environmental and ecological economists already agree that society should have zero tolerance for highly toxic chemical wastes and radioactive substances for which the ecosphere has no measurable assimilative capacity. Such substances should simply be banned or phased out (as was the case for ozone-depleting CFCs and chlorinated pesticides in much of the world).

The fact that ecofootprint analysis does not incorporate all human ecological impacts merely confirms that no single index can represent every aspect of any phenomenon. It certainly does not invalidate the findings of existing analyses. Rather, it suggests that, despite the alarming magnitude of many national ecofootprints, present calculations almost certainly underestimate actual ecosystem appropriations and that methodological improvements and extensions may well result in even larger ecofootprints. As it is, ecofootprinting provides unambiguous results (e.g., it shows that the world is in overshoot, quantifies the increasingly unsustainable entanglement of nations, reveals the extent of ecological inequity, and challenges material growth as the best way to address poverty) and suggests clear directions for policy if nations and the world are serious about achieving equitable sustainability. Increasing the accuracy and scope of the analyses may add to our sense of urgency but will not likely shift the general direction of needed policy initiatives.

Ecofootprinting is too Simplistic

Some commentators have argued that the ecofootprint concept oversimplifies both nature and society and has little predictive value. It merely generates static estimates of a single aggregate variable.

Again, it is true that footprint analysis is not dynamic modeling and cannot directly project the effects of technological change or social adaptation. However, rigorous modeling and prediction were never the intent. Ecofootprinting provides a simple ecological camera – each analysis is a snapshot of current demands on nature, a portrait of how things stand right now under prevailing technology and social values.

This in itself is important information. Current snapshots indicate that many countries are in a potentially risky eco-deficit, that humanity has already significantly exceeded global carrying capacity, and that some people contribute significantly more to ecological overshoot than do others. This is sufficient to suggest approximately how much we must reduce our consumption, improve our technology, redistribute wealth, or change our behavior to achieve sustainability.

Of course, once an initial baseline has been established, subsequent ecofootprint assessments can contribute to time-series studies – repeated snapshots over years or decades – to monitor progress toward, for example, reducing national

ecological deficits or closing the global sustainability gap. (After all, even a motion picture is a series of snapshots.) As shown by the Global Footprint Network's annual updates of the ecofootprints of most of the world's nations, such sequential analyses are capable of demonstrating the actual effects of new technologies, significant economic policy initiatives, changes in income or population, and shifts in consumer behavior or cultural values. We can also assess the potential impacts of alternative technologies, policy changes, or settlement patterns on population ecofootprints using simulation studies. If we know how some technological innovation or policy initiative is likely to affect the consumption of critical commodities, the standard calculations can be used to address such questions as: how would a shift from fossil fuels to biomass fuels or solar energy affect a population's ecofootprint? Would a general shift to vegetarianism or organic foods reduce our food footprint?

To summarize this point, EF analysis is not intended to provide a dynamic window on the future but rather a snapshot in time. As such, it can both help to assess current reality and to test alternative what-if scenarios on the road to sustainability.

On a related matter, some critics have stressed that while both the ecosphere and the economy are complex dynamic systems, ecofootprint analysis ignores the wide-ranging implications of complexity theory. This comment, while true, misses two points. First, ecofootprinting was not intended to provide a comprehensive picture of socioecological systems. It was created to quantify just one key indicator of humanity's engagement with the rest of nature – our dependence on ecosystems services – heretofore largely ignored in sustainability policy debates. To the extent that this index is reliable and has policy relevance to sustainability, it can be used in conjunction with economic, social, or other indicators in a comprehensive approach to the issues at hand.

Second, although science has certainly gained important insights from complex systems theory – the behavior of dynamical, self-organizing, adaptive systems often confounds standard forecasts and derails simplistic approaches to ecosystems management – the fact remains that simple models are adequate for many phenomena. Under these circumstances, Occam's razor still applies: there is no need to derive a complex explanation where a simple one suffices.

For example, one can hardly imagine a better example of a complex human-dominated system than the world's great cities. Cities are a marvel of biophysical, economic, political, social, and cultural subsystems that somehow come together to function as a complex, dynamic, integrated, self-organizing whole. Nevertheless, if any city as currently conceived were enclosed in an impermeable glass dome whose base coincided with its political or geographic boundaries, it would rapidly disintegrate.

The explanation is simple – the city would simultaneously be starved of resources and forced to suffocate on its own wastes. This is because most of the ecosystem functions and biophysical processes supporting the city lie outside our hypothetical bell jar. Ecofootprint analysis measures the city's (region's, country's, etc.) dependence on nature's services and estimates the de facto ecosystem area needed to produce them. (Remarkably, most studies of cities-as-systems still ignore this

critical biophysical dimension.) By accounting for the city's full metabolic demand, ecofootprint analysis shows that the built-up core – the nominal city – is only a tiny component of the total system. Cities are dissipative structures totally dependent on the biocapacity of a vast, increasingly global hinterland hundreds of times the size of the city itself. The consumptive core and the productive hinterland together constitute the complete urban ecosystem. There is certainly room to debate the methods used to make such EF estimates. However, we do not need to know anything about city governance or the complex relationships among its physical and socioeconomic subsystems to predict the collapse of our city-in-a-jar, to quantify its dependence on distant ecosystems, or to assess its vulnerability to global change.

Is the Carbon (Energy) Footprint a Real Land Use?

For many high-income industrialized countries, the fossil energy or carbon footprint may make up half of the total ecofootprint. Modern society makes heavy demands on available carbon sinks. However, because science cannot account fully for the global carbon budget and there is dispute over the relative roles of terrestrial and marine ecosystems in carbon sequestration, some critics see energy footprint calculations as unreliable or hypothetical. Others do not regard carbon assimilation as a real land use. Still others, mostly techno-optimists, suggest that existing ecofootprint estimates exaggerate the impact of prevailing energy use while not taking renewable energy into account.

The first criticisms reflect our cultural bias that land use requires physical occupancy or the consumption of some tangible product of the land. People are unaccustomed to thinking of the provision of other (particularly nonmarket) biophysical services of nature, no matter how essential to sustainability, as effective uses of landscape. From the perspective of thermodynamic law and mass balance, it is this cultural bias that needs adjustment, not ecofootprint theory. All energy and material use is throughput, implying the generation of wastes, and to the extent that the assimilation and recycling of those wastes (including carbon dioxide) requires an exclusive dedication of land or water, it is a legitimate component of ecofootprint calculations.

As it happens, carbon dioxide is the greatest waste output by weight of industrial economies. Also, although the details of the carbon budget may be in dispute, there is no question that: (1) carbon dioxide levels are increasing in the atmosphere and that (2) these increases represent about half of current carbon emissions from fossil fuel combustion. This implies that available land and water carbon sinks are insufficient to sequester all anthropogenic carbon dioxide at current rates of emission. In ecofootprint terms, humanity's demand for natural sequestration services exceeds available supply. We are running a global carbon sink deficit in exactly the same sense that many countries run a food-land deficit.

All of which is to say that the notion of carbon sink lands is not hypothetical even if the real thing is in short supply. Energy footprint calculations therefore estimate the area of dedicated carbon-sink forests that would be necessary to assimilate a study population's carbon emissions, assuming average estimated carbon sequestration rates of the world's growing forests. It is precisely such thinking that has led

various electric utilities to plant dedicated carbon sink forests to offset the emissions from their fossil fuel-burning generating plants. Similarly, some countries have contemplated dedicated carbon sink forests as an alternative to reducing their carbon emissions or as a way to generate credits in regional or future global carbon trading schemes. (Carbon trading in various forms has become commonplace.)

Having established the legitimacy of carbon sink estimates, we should note that a dedicated carbon sink forest is an exclusive land use insofar as it cannot be harvested for any purpose such as pulp and paper production that would quickly release sequestered carbon back into the atmosphere.

Finally, we should recognize that any alternative to fossil fuels will also generate an energy ecofootprint and that the effect of any wholesale shift to renewable energy technologies will show up in subsequent ecofootprint estimates. Techno-optimists should note that the new energy footprints will not necessarily be smaller than today's carbon footprint. For example, consider the ecofootprint of corn-based ethanol production, which has become a major industry in the US. The ethanol footprint includes not only a fuel-crop growing area larger than the carbon sink area required to sequester the carbon emissions from an equivalent amount of fossil fuel but also a de facto carbon sink to assimilate the carbon emitted by the various fossil-fuel based technologies (mechanized cropping, diesel irrigation, transportation, biomass distillation, etc.) used to make the ethanol. Various studies suggest that corn ethanol production is a net energy sink or only a marginally positive energy source – it takes as much or more fossil energy to produce the ethanol as is contained in the product – hence, the carbon footprint of a gallon of corn ethanol is more or less the same as that of the fossil fuel the ethanol was supposed to displace. In total, therefore, aggregate energy ecofootprint of the so-called renewable corn ethanol is much larger than the carbon ecofootprint from burning an equivalent quantity of fossil energy. So much for sustainability. The main point is that all energy sources have an ecofootprint, and when subjected to full life-cycle analysis, at least some renewable energy sources may not perform any better than fossil fuels in ecofootprint terms.

Ecofootprinting is Antitrade and Antigrowth

Some critics, particularly neoliberal economists, suggest that ecofootprint analysis is biased against cities, trade, and globalization. Others argue that the method is neo-Malthusian because it raises concerns about carrying capacity and suggests that there are limits to growth. In fact, however, ecofootprint analysis is merely a number-crunching tool whose output is subject to alternative interpretations and policy responses. The numerical results do not, in themselves, reflect an antitrade, antiurban, or antigrowth bias.

That said, there can be little question that many sustainability analysts are alarmed by the findings of ecofootprint studies. The results show unambiguously the biophysical dependence of densely populated, high-consuming regions/countries on other countries and the global commons; they reveal that many countries are running significant ecological deficits and that the world as-a-whole is in overshoot. Given that we live in an era of accelerating global change and uncertain geopolitics, it seems reasonable to conclude that trade

dependence carries increasing risks and that greater regional self-reliance might be a good thing. Similarly, is rampant overshoot not sufficient grounds to question global society's so far unwavering commitment to continuous economic growth?

The problem is that all such reasoning is anathema to unreformed economists and other expansionists who favor unrestrained growth facilitated by trade and for whom carrying capacity is a nonissue. Many critics of ecofootprinting thus seem to reject the method, not on theoretical or methodological grounds, but rather because of the questions it raises and because logical answers to these questions confront their own disciplinary or ideological biases. By reopening the debate on carrying capacity and exposing the downside of globalization and trade, ecofootprint analysis challenges the core developmental economic ideology of our time.

Epilog

Whatever its weaknesses, the EF concept is strong enough to have captured both the scientific and the popular imaginations. It is now being applied as an assessment tool by nongovernmental organizations and government agencies in towns, cities, and countries around the world. A small industry of consulting firms has sprung up to develop and commercialize various products based on the ecofootprint concept.

Ecofootprinting seems to concretize the human ecological crisis in a way other energy and material flows studies do not. The ability to compare the demand for biocapacity with supply is an important factor. Knowing our EF not only makes us conscious of our personal contribution to global change but also makes us responsible for doing something about it. Pluralistic democracies can work only if the public are well informed about key policy issues and have a keen sense of their capacity to make a difference in improving the human prospect and those of other species. To the extent that EF analysis helps to generate a more ecologically literate and politically active populace, it will have achieved its most important objective.

Glossary

Coevolution Process of reciprocal genetic changes in interacting species that result from the mutual selection pressures that strongly interacting species can exert on one another.

Keystone species Species whose presence fundamentally alters the structure or function of an ecological community or ecosystem.

Metapopulation Collection of subpopulations connected by dispersal. Subpopulations within a metapopulation may undergo local extinction and subsequent recolonization.

Threshold theorem of epidemiology If the density of susceptible individuals in a population falls below some critical threshold, then a disease may not be able to maintain itself in the population.

Historical Development of Ecology's Central Concepts and Theories

Ecological theory has three major origins: (1) attempts to manage fisheries, pests, or wildlife, (2) explorations of patterns in nature—especially spatial pattern and the apparent order of species assemblages, and (3) investigations of “the balance of nature” (and how that balance can be disturbed). To some extent, ecological theories developed separately in the sub-disciplines of plant and animal ecology. For example, quantitative plant ecologists tended to focus on patterns of plant dispersion and relationships between individual plants and their environments, whereas animal ecologists focused more on population dynamics. But the most important early ecological models came from neither plant nor animal ecologists; instead these pioneering models were largely contributed by scientists from other fields, such as physics, mathematics, and human demography.

The acceptance of mathematical approaches into mainstream ecology has been slow (and some might argue that mathematical theory is still not accepted by many ecologists). The reluctance of ecologists to embrace mathematical models reflects the different ways that empiricists and theoreticians view the world. In particular, whereas field ecologists are typically concerned with the uniqueness of their study systems and pay attention to the role of history and “details,” mathematical ecologists often neglect the role of history and gloss over details to arrive at more general results. Fortunately, there has been increasing reconciliation between the theoretical and empirical approaches to ecology, largely because

modern ecological theory has matured enough to allow examination of how details such as age structure, spatial heterogeneity, or environmental variation alter the generalities derived from more simple models. In addition, recent ecological theory relies less on “equilibrium analyses,” which tended to downplay historical effects.

Whereas many branches of natural science are grounded in some core body of theory and first principles, this is not the case for ecology. Instead, ecological theory is remarkably varied and discordant, with natural selection as the only fundamental “law.” Moreover, although one could argue that little in ecology makes sense without the perspective of natural selection, there is a great deal of useful ecological theory that never makes any contact with evolutionary principles. Thus, even though all ecologists accept evolutionary theory, different subfields of ecology do not share a common view of the most important theoretical questions (such as ecosystem analysis versus population biology). However, in spite of this notable lack of a single unified and ascendant ecological theory, current attention to conservation and resource management has stimulated the practical integration of models that range from evolving gene pools to ecosystem nutrient cycling.

Population Dynamics

Births and deaths are the bottom line of ecology—this is because variation in birth and death rates determines the distribution, density, and dynamics of populations. However, most population models avoid tabulating particular sequences

of births and deaths and instead keep track of average rates of change. In most cases, models of population change are not precise forecasting tools, but rather are conceptual frameworks with which to understand when a population is expected to stay constant as opposed to fluctuate wildly. Models are also valuable for asking how external factors such as harvesting and habitat destruction might alter a population's long-term fate. Two fundamental features of population dynamics are inescapable:

1. Because of resource limitation, per capita rates of change for populations decline with increasing density.
2. If there is any time lag in the response of demographic rates to declining per capita resources, the population may overshoot their resources, then crash to low levels, then rebound, only to repeat the process again.

Formal mathematical representations of these principles have led to elegant models of nonlinear population dynamics. "Nonlinear" refers to the fact that the rate of change in populations varies nonlinearly with changes in population density. As a consequence, under a wide variety of circumstances populations are prone to fluctuate, sometimes so erratically that a graph of numbers through time would appear random, and such that any small changes in initial population size become amplified through time (an attribute called chaotic dynamics). This theoretical result is now widely appreciated by ecologists, but its illumination in the 1970s represented a major advance in the field. First, it emphasizes that populations may fluctuate without any environmental or climatic variation. Second, the phenomenon of chaos illustrates how complicated and unpredictable population dynamics can arise in the simplest systems, if nonlinear feedbacks are strong enough to cause the overshooting of equilibria followed by pronounced population crashes. Prior to the development of a theory of chaotic and nonlinear dynamics there was a tendency to always look to the external environment as the cause of population fluctuations, and to think that complicated patterns of fluctuation must have complicated explanations.

Applications of population theory have largely focused on three types of species: rare species that are of conservation concern, species that reach extraordinarily high population densities ("outbreaks") that cause severe damage to crops or forests, and finally species that are harvested by humans, especially many fish species.

To assess threats to rare species, ecologists have developed a suite of analytical tools collectively known as population viability analysis (or PVA). PVAs are commonly used to estimate the probability of extinction under a range of alternative management strategies or to quantify the minimum number of individuals that will ensure survival of the species. PVA models may incorporate the effects of environmental and demographic stochasticity, catastrophes, and spatial structure and movement (*see Spatial Patterns*). One approach that has been quite successful entails detailed demographic analyses that keep track of the birth and death rates for groups of similar individuals. When the groups are defined by age of the organisms, a life table can be developed. However, demographic matrices are flexible enough to incorporate groups based on size, stage, or sex, as

well as age. The principal advantage of demographic matrices is that one can ask how sensitive the growth rate for the entire population is to changes in the survival or fecundity of a particular class of individuals. This approach is being used increasingly to compare the efficacy of alternative management scenarios. Analyses of this nature have revealed that adult survival is generally a very sensitive demographic parameter for long-lived species, whereas fecundity is often the most sensitive parameter for shorter-lived species. These findings have shaped a number of conservation decisions—for example, a demographic matrix applied to loggerhead sea turtles made it clear that even substantial improvements in the survival of baby hatchling turtles would provide little benefit to the turtle population, whereas elevating the survival of adults could dramatically help this threatened long-lived species.

For outbreaking or pest species, population ecologists have asked what factors lead to population outbreaks and whether certain life-history traits are shared among those species with a propensity to outbreak. The goal of this research is to determine how best to control these species and prevent future outbreaks from occurring. One quantitative focus concerning outbreaking species has been on the role of time lags. Time lags can occur when, for example, a population does not respond immediately to changes in its own density, perhaps because the individuals store up energy reserves. Alternatively, a population may lag in its response to one of its natural enemies, such as a predator or a disease. Any such time lag, especially when combined with a high potential for population growth, can lead to dramatic oscillations in population abundance.

Finally, for harvested species there has been a focus on determining the maximum sustainable yield (MSY) that can be harvested from a population without placing it at risk of extinction. Clearly most natural populations do not grow without bound, but rather are regulated around some equilibrium density, called the carrying capacity of the environment. This assumption of density-dependent population growth (a reduction in the per capita rate of population growth as population density increases) is central to the calculation of MSY. In particular, theory predicts that the largest number of individuals can be sustainably harvested when a population is maintained at approximately half its carrying capacity. Although density dependence is a central tenet of population ecology and particularly of fisheries management, actually detecting density dependence from a time series of population abundance estimates remains difficult, and discussions about the appropriate methodology have been contentious. A large part of the difficulty in detecting pattern is the random variation inherent in estimates of population size. While part of the variation is due to observer error, a large fraction is often due to random fluctuations in the environment that change either the population growth rate or the equilibrium population size from one year to the next. It is straightforward to investigate in theory the interplay of density dependence and these external sources of variation. The bigger challenge lies in developing management models for real-world data sets in which the apportionment of variation among observer error and different effects of environmental variation is unknown. Fisheries biologists have made the

greatest progress in this area, but the theory is still incomplete; it remains especially challenging to connect models of population dynamics to economic models that integrate the biological and economic aspects of resource management.

Theories of Species Interactions

The traditional core of mathematical ecological theory involves dynamical models of pairwise interactions between a predator and its prey, or between two competing species. Both of these types of interaction lead easily to the extinction of species—either because a predator imprudently consumes its entire food base or because a superior competitor usurps so much of the resources that other species cannot make a living. Not surprisingly then, the focus of species-interaction theory has been to ask what processes mitigate the tendency toward extinction in these antagonistic interactions.

Although the elimination of an inferior competitor seems inherent to competitive interactions, in nature we regularly find many species coexisting. Early on, theoretical ecologists suggested that coexistence generally occurs only when the populations of the two species are limited by different resources. In other words, coexisting species must occupy distinct ecological niches. The concept of the ecological niche motivated numerous attempts to quantify just how different two species must be in order to coexist. Measures of various traits related to resource use, such as beak size, body size, and habitat preferences, were often invoked as evidence for “niche partitioning” (the use of different resources by potentially competing species). Careful attention to such data indicated that this evidence was often not as clear-cut as initially assumed, and research was devoted to alternative explanations for the coexistence of competitors. A second generation of competition models made it clear that competing species may readily coexist without any niche partitioning, as long as some form of disturbance interrupts the exclusion of the inferior competitor. Such disturbance can take the form of predation, or abiotic factors such as storms or droughts. Implicit in disturbance-mediated coexistence is the concept of a trade-off between the ability to be a superior competitor and the ability to recover from a disturbance.

As with competition models, early models of predators and their prey suggested that stable coexistence would require certain special conditions. In the absence of these conditions, predators tend to drive their prey to extinction, and then, having exhausted their food supply, go extinct themselves. One answer to the dilemma of predator–prey coexistence was provided by a classic series of laboratory experiments using predatory mites and their mite prey that live on oranges. These experiments demonstrated that, in a simple “landscape” (a tray of oranges), the mite predator was able to quickly find and consume all of its prey, leading to the extinction of both species. However, more complicated laboratory microcosms that impeded the predator’s movement could prolong the coexistence of the predatory and prey mites by as much as an order of magnitude—slower predator movement allowed the prey to stay “one orange ahead” of predators and enjoy a temporary refuge from attack. Subsequent mathematical models have made it clear that this is a general principle:

predator–prey interactions can be stabilized by any attribute that affords prey some refuge from attack. The refuge can take the form of patches of habitat, or age or size classes of individuals that enjoy low attack rates. With spatial refugia, there is still a tendency for predator–prey systems to fluctuate locally, but different patches will fluctuate out of phase so that the entire collection of patches never goes through a phase in which prey are everywhere absent.

In the last three decades predator–prey theory has been modified to model plant–herbivore and host–disease (or parasite) interactions. These models are similar to classic predator–prey theory in structure and in terms of the possible dynamics associated with the interactions. However, there are also important differences. First, the effects of herbivory are not as obvious as those of predation—individual plants are usually not killed outright by herbivory, and some plant species may actually perform better after being partially consumed. Also, studies of herbivory have typically had more of an evolutionary emphasis in focusing on how herbivores act as selective pressures on plant traits, especially plant structural and chemical defenses.

Host–disease interactions also have been a rich subject for mathematical modeling, with much of the initial theory originating from work on the epidemiology of human diseases. Epidemiological models reveal that disease spread depends on the transmission rate, virulence, latency, and infectious period of the disease, as well as the density of susceptible hosts. More specifically, a disease will be unable to persist if the density of susceptible hosts falls below a threshold value. Immunization programs represent an application of this result, sometimes called the “threshold theorem of epidemiology.” Immunization can lead to the elimination of a disease, because if a sufficiently large percentage of the population is vaccinated, an infected individual will, on average, fail to transmit the disease to a susceptible host before the infected host either recovers or dies. Epidemiological models further reveal that diseases can potentially maintain host populations at low levels or cause pronounced cycles in the host population.

Although much theoretical work has focused on interactions within species pairs, species do not, of course, occur only in pairs in nature. Most natural communities include scores or hundreds of different species, simultaneously interacting with one another to various degrees. Recently, increased attention has been paid to relatively complex interactions occurring among multiple species. The food web or, more generally, interaction web has proven to be a useful way to visualize the interactions among large groups of species with vertical links representing trophic interactions and cross-links representing competitive or mutualistic interactions (Figure 1). Enormous effort has been focused on understanding the relationship between the patterns of connections among species and the traits of the community itself. However, interactions vary in strength, and it is clearly as important to measure the relative strength of an interaction as to merely document its presence.

The study of multiple species interacting simultaneously has led to the recognition that indirect effects can be important determinants of community structure, and several distinct types of indirect effects have been distinguished. For example, apparent competition occurs when two species appear to be

Figure 1 Interaction webs demonstrating three types of indirect interaction: (a) apparent competition; (b) predator-mediated competition; and (c) trophic cascade, as well as (d) a more realistic, species-rich interaction web depicting the major interactors associated with fireweed at Mt. St. Helens, in Washington.

competing because, as the population of one species grows, the abundance of the other declines. However, these changes in abundance are not caused by direct competition, but rather by a third species that consumes each prey species in proportion to its relative abundance (see **Figure 1a**). A second type of indirect interaction occurs when a consumer species indirectly affects a species via its competitor. For example, a consumer that limits a competitively dominant species may indirectly benefit a competitively inferior species (see **Figure 1b**). A third type of indirect effect thought to be common and important is a trophic cascade. An example of a trophic cascade is when a carnivore species limits the abundance of herbivores, resulting in luxuriant plant growth (see **Figure 1c**). The presence of a trophic cascade is demonstrated when removal or exclusion of the carnivore results in a dramatic increase in the herbivore population and the subsequent decimation of plant biomass. Field studies are increasingly documenting the ubiquity and importance of indirect interactions. However, the difficulties encountered when studying the simplified food webs depicted in **Figure 1a–c** are greatly exacerbated when trying to understand the interactions occurring in more realistic, species-rich food webs (see **Figure 1d**). The significance of this is that simple ecological experiments that focus on just one or two species may fail to reveal the important determinants of community structure.

In sum, theories of species interaction have largely focused on the problem of coexistence or, as it has also been called, the paradox of diversity. These theories address how so many species manage to coexist in nature, whereas simple lab experiments and mathematical models so often predict

extinction. A major shift in thinking about this problem was the recognition that natural populations are subjected to environmental variability and other disturbances that can prevent the process of competitive exclusion. In addition, the complexities of multispecies interactions, including indirect interactions, can promote the coexistence of species.

Although the earliest models of species interactions seem abstract and disconnected from reality, ecology has a rich tradition of using experiments to test models. For example, the Russian biologist G. F. Gause pioneered the testing of species-interaction models using laboratory cultures of protozoans and yeast in which he could follow population dynamics on the time-scale of weeks, and thus could rapidly see whether or not a species could persist in his experimental systems. When examining competition between *Paramecium* species, Gause often observed that some species could drive others to extinction, a process termed competitive exclusion (and a result predicted in theory by the differential equations that depict continuous reproduction of two protozoans in competition for the same resource). Currently, laboratory microcosms involving protozoan communities are receiving fresh attention—nowadays these experiments are aimed at testing models of multispecies interactions and interaction webs.

Theories of Biodiversity

Biodiversity is the variety of all living things, and most commonly refers to the number of different species in a particular

area. Ecologists have documented striking patterns in the number of species occurring in different regions of the planet. For example, for most groups of species, there is a strong gradient of declining diversity from the equator to the poles, and the vast majority of species are therefore concentrated in tropical and subtropical regions.

Ecologists have proposed a variety of mechanisms that may be responsible for generating global patterns of biodiversity. For instance, areas with more varied landscapes and more topographic relief tend to support more diverse species assemblages than more uniform areas. Thus, spatial heterogeneity is likely to provide more ecological niches for species to occupy and therefore allow more species to coexist. As discussed earlier, classic ecological theory predicts that competitive interactions among species should lead to competitive exclusion and therefore reduced biodiversity. Several of the proposed mechanisms for global diversity patterns focus on forces that counter the process of competitive exclusion. Accordingly, it has been hypothesized that tropical regions harbor many species because their benign climate favors diseases and predators—these predators and diseases increase species diversity by attacking competitively superior species, thereby allowing weak competitors an escape from competitive exclusion. Disturbance is thought to similarly preclude competitive exclusion, although disturbance that is too intense or that occurs too frequently may result in reduced biodiversity. The idea that diversity should be reduced when disturbance is either too rare or too frequent has been termed the intermediate disturbance hypothesis.

Another robust pattern of biodiversity is the observation that islands generally have fewer species than mainlands, and that larger islands tend to have more species than smaller islands. R. H. MacArthur and E. O. Wilson proposed the equilibrium theory of island biogeography to account for this pattern. According to this theory, there is a balance between colonizations of new species on islands and the subsequent extinctions of established species. On larger islands, colonizations are relatively more frequent and extinctions are less frequent, resulting in a higher equilibrium number of species on larger islands.

Human activities such as the direct harvesting of species, introductions of alien species, habitat destruction, and various forms of habitat degradation have greatly accelerated the loss of biodiversity. Consequently, current extinction rates are estimated to be 100 to 1000 times higher than pre-human extinction rates. This extinction crisis has spurred a great deal of scientific interest in the biological and ecological functions of biodiversity. Organisms are responsible for a variety of ecosystem functions, including maintenance of the gaseous composition of the atmosphere, regulation of the global climate, generation and maintenance of soils, and recycling of nutrients and waste products. However, it is not obvious whether these biological services require many species or only a handful of species. Much current research is focused on understanding how much (if any) diversity we can afford to lose yet still maintain the necessary ecosystem functions (*see Ecosystem Theories*).

Some species play obviously important roles in ecosystems—the addition or deletion of these “keystone” species leads to dramatic changes in ecosystem functions such as

productivity or nutrient uptake. However, most species probably do not exert such important effects on ecosystems. In other words, it may be possible to lose a number of species from an ecosystem with little overall impact on ecosystem function. This could be the case if several species that perform approximately the same function are present in the original ecosystem. The situation where multiple species play a similar role has been termed “species redundancy.” If species redundancy is a common phenomenon, ecosystem function should be largely independent of species diversity, so long as major functional types are represented. Thus, when one species is lost from an ecosystem, some other species with a similar function may become abundant and compensate for the lost species, leaving the ecosystem as a whole relatively unaffected. Indeed, ecosystem processes often do remain stable despite large fluctuations in the abundance of the various species involved. The term species redundancy may seem to imply that all species are not necessary for an ecosystem to function properly. However, species redundancy may in fact be an essential feature for the long-term health of ecosystems, and the importance of any particular species may only become evident during the occurrence of rare, drastic events.

Spatial Patterns

Spatial patterns and habitat patchiness or heterogeneity have spawned a host of concepts that try to both describe these spatial patterns and explain their impacts and sources. The two most important general results of spatial theory in ecology are:

1. The fact that species interact in spatially extensive and patchy worlds creates opportunities for persistence and coexistence of species that would otherwise not exist.
2. In uniform environments, the interplay of dispersal and nonlinear population dynamics can produce complex spatial patterning in population densities, and this patterning can itself promote coexistence in predator–prey or competitive interactions.

More generally, spatial theory emphasizes that it may be impossible to understand ecological processes and interactions if the focus and scale of a study is too small. This is an important caution, given the fact that many experimental ecology studies are conducted at scales of less than 1 m².

One of the most important practical applications of spatial theory stems from the use of metapopulation models in conservation biology. Metapopulation theory describes a species as a collection of populations (or patches) in which there is turnover due to local extinction and subsequent recolonization by dispersing individuals, and in which the fate of a species can only be understood by tracking the fate of a collection of populations or patches, as opposed to a single local population or patch. Metapopulation models are of considerable importance in conservation applications because they identify critical thresholds for habitat destruction or for the creation of barriers to plant and animal dispersal, thresholds that, once crossed, imply doom for a species (because colonization becomes too infrequent to counterbalance local extinctions). It is obvious to anyone who has looked out an airplane window that one of humankind’s major impacts

on the world is to destroy habitats and to create ever more fragmented landscapes dissected by highways, agricultural fields, and commercial or residential developments that surely hinder the dispersal of species. If this trend proceeds too far, metapopulation theory predicts the slow but inexorable loss of species. Spatially detailed models of human-modified landscapes are increasingly being used to identify strategies for land use and human development that will minimize the undesirable effects of habitat loss and habitat fragmentation. The two most common strategies involve clustering of habitats and the protection of dispersal corridors.

At a more theoretical level, spatially explicit models of species interactions indicate that the interactions themselves can result in pattern formation. For example, high rates of predation combined with limited prey dispersal can result in a dense patch of prey surrounded by a zone that is relatively devoid of prey due to intense predation. This “ring” of intense predation can limit the spread of prey populations. It is important to realize that these spatial patterns can emerge without any underlying environmental heterogeneity. Spatial patterning can allow more species to coexist because the species occupy different portions of the pattern. However, the opportunity for spatial segregation of species into different characteristic portions of spatial patterns requires sufficiently large habitats—if habitats are carved into patches that are too small, patterns cannot be generated, and opportunities for coexistence will be lost. Thus, theories of pattern formation reveal yet another mechanism by which biodiversity can be maintained, and conversely a route by which biodiversity can be degraded.

Scaling Laws

Because ecological processes operate across a huge range of scales, there have been numerous attempts in ecology to identify scaling laws—laws that allow us to study phenomena on one scale and predict those same phenomena at different scales. Just as important as identifying rules for extrapolating across scales is the idea that there are critical spatial scales at which scaling laws break down and processes fundamentally change in character.

An especially good example of successful extrapolation across scales concerns the prediction of the rate at which exotic species invade new areas and expand their ranges. Simple invasion models extrapolate short-term observations of dispersal (over the scale of one year or less and involving the movements of single individuals) to the broad expanse of an entire species range after decades and over thousands of kilometers. For organisms as diverse as muskrats and cabbage butterflies, invasion models have successfully used small-scale and short-term data to predict long-term rates of range expansion.

To quantitatively examine the legitimacy of extrapolations across scales, it is often useful to graph the variance of a measured variable as a function of the spatial scale at which it was measured. For example, population density could be measured in anything from 1-m² quadrats to hectare plots, and the variance in density (per unit area) among plots is expected to decline with increasing plot size. The rate of this decline is a measure of spatial correlation. However, marked

changes in the slope relating variance in population density to measurement scale indicate some fundamental shift in biological processes—such as a shift from patterns generated by the dispersal range of a plant’s seeds to patterns generated by large-scale climatic heterogeneity. Such nonlinear relationships between variance and scale indicate circumstances where it may not be appropriate to extrapolate across scales.

Most ecologists continue to conduct research at one and only one scale. Although theories regarding scaling laws are still in their infancy, they plainly draw attention to the fact that any extrapolation across scales is tenuous, and can only be justified if the processes have been studied or measured at more than one scale.

Ecosystem Theories

Ecosystem theories focus on patterns of energy flow, nutrient cycling, and the factors that control or limit the rates of these processes and the stability or predictability of these processes through time. To assess the flow of energy and nutrients, it is useful to recognize that organisms fill different trophic roles: autotrophs (usually plants) acquire energy, usually from the sun, and nutrients from nonliving materials, heterotrophs derive energy and nutrients by consuming living matter, and decomposers transform once-living materials back to their inorganic forms. Both nutrients and energy flow from autotrophs to heterotrophs and decomposers, and the connections among these groups, constitute a food chain or food web.

The trophic interactions among species affect the rates of ecosystem functions, including biogeochemical processes, the flow of nutrients, water, and atmospheric gases, and the processing of energy through ecosystems. Species are the key working parts of ecosystems, and therefore biodiversity must be related in some way to ecosystem function. Certainly ecosystems would not function if all species were lost, but it is unclear just how many species are necessary for an ecosystem to function properly. The current extinction crisis has prompted ecologists to assess the relationship between biodiversity and various ecosystem properties. Evidence regarding the importance of biodiversity for ecosystem function largely comes from comparing ecosystems that naturally differ in the number of species present. More recently, ecologists have undertaken more controlled manipulative experiments in which the number of species has been directly varied. Several studies have demonstrated that various measures of ecosystem function, such as production of biomass and nutrient uptake, increase as the number of species present increases. However, some studies also report no effect or even negative relationships between biodiversity and ecosystem processes.

Although some evidence suggests that biodiversity increases or improves the overall functioning of ecosystems, the underlying mechanisms remain unclear. For example, a positive relationship between species diversity and productivity could result simply because including more species increases the chance of including particularly productive, or fast-growing, species. Alternatively, a diverse group of species may use the available resources more efficiently, because each species has a slightly different strategy, resulting in higher overall growth.

A second commonly purported benefit of biodiversity is that more diverse ecosystems may be more stable compared to species-poor ecosystems. Stability can be defined at the community level as fewer invasions and fewer extinctions, meaning that a more stable community will contain a more stable composition of species. However, stability can also be defined at the population level as reduced fluctuations in population size, meaning that a more stable population will contain a more constant number of individuals.

The idea that biodiversity confers stability to ecosystems has enjoyed a long and controversial history. Ecologists initially hypothesized that diverse ecosystems were more stable than those with fewer species because, it was reasoned, with more species in an ecosystem, there are more paths through which energy and nutrients can flow. Consequently, in diverse ecosystems each species should be less affected by changes in the abundance of other species, leading to higher overall stability. However, mathematical models exploring the relationship between biodiversity and population stability indicated that higher species diversity generally reduces the stability of population dynamics of individual species. The conflict between these modeling results and the original intuitions of ecologists remained unresolved for many years.

Recent experimental manipulations of species diversity have helped to resolve this long-standing controversy. In particular, several manipulations of plant and microbe diversity have been performed to examine the stability of various measures of ecosystem function over time. Generally, such studies have shown that, although the abundance of individual species fluctuates more dramatically in high-diversity ecosystems, the total abundance or productivity of all species combined is actually more stable. These empirical results are consistent with both views of diversity and stability. First, the fact that individual species fluctuate more in diverse systems supports the results of mathematical models regarding diversity and stability. On the other hand, the observation that aggregate attributes such as productivity become more stable with increased diversity supports the intuition that multiple pathways for energy (high diversity) foster stability.

Although the relationship between biodiversity and ecosystem stability is becoming increasingly clear, the mechanisms generating this pattern are not. In particular, diverse groups of species may be more stable because complementary species compensate for one another. Alternatively, variation in aggregate measures such as total productivity may increase with richness due to averaging of random fluctuations in the growth of each species. On the basis of simple probability theory, it is expected that as more independently varying species are summed together, the more stable will be the sum of their abundances. The strength of this averaging effect depends on correlations among the species' fluctuations, but a positive relationship between biodiversity and the stability of aggregate measures of ecosystem function should almost always be expected, simply due to averaging.

Evolutionary Theory in Ecology

Evolutionary theory has entered ecology in two major areas: the evolution of species attributes and how they might vary in

a predictable manner, and the coevolution of interacting species, such as the evolution of virulence and resistance in host–pathogen interactions.

There is often a remarkable matching between the traits of organisms and the local conditions in which they live. Ecologists and population geneticists alike have worked to identify the factors contributing to or preventing the adaptation of populations to various aspects of their local environments, including food sources, predators, and microclimatic conditions. Reciprocal transplant and common garden experiments have been the major tools used to test for local adaptation. In particular, there is interest in the balance between selection for locally adapted traits and the immigration of individuals with nonadapted traits into the population. This balance between differentiating selection and the homogenizing effects of migration can create a difficult conundrum for conservation biologists—for a rare species that exists in several small populations, it might be better to pool all the individuals together to bolster the size and viability of a single population. Alternatively, the subpopulations might be so genetically distinct and locally adapted to their environments that pooling the individuals might actually harm the species. Thus, one of the more difficult challenges in conservation is to balance the short-term viability of a species with preservation of its long-term evolutionary potential.

As a species evolves to become locally adapted to other species in its environment, it can exert selection pressure on the co-occurring species, leading to changes in the traits of these species with which it interacts. The reciprocal evolution of two species in response to one another is called coevolution. The term coevolution was originally coined to describe the presence of toxic compounds found in plants and the ability of butterfly species to detoxify these compounds. Indeed, many of the best-known examples of coevolution involve reciprocal changes between adversaries, a sort of ever-escalating “arms race” as might occur between a predator and its prey or between a parasite and its host.

Plant breeders try to directly manipulate the revolutionary process that occurs between crop plants and the herbivores and pathogens that attack these plants. Selective breeding is used to maximize the defenses naturally present in crop species and, more recently, genetic engineering has allowed breeders to co-opt defenses of very distantly related organisms and introduce completely novel defense traits to crops. Unfortunately, when highly defended crops are planted over the enormous spatial scales of modern farms, herbivore and pathogen species tend to quickly evolve resistance to the plant defenses. Thus, an important application of evolutionary ecology involves determining how we can best deploy plant defensive traits such that evolution on the part of plant pathogens and herbivores does not make the plant defenses obsolete. Theory suggests that alternating plantings of crops with distinct defensive traits may reduce the ability of herbivores to evolve resistance. In addition, incorporating combinations of defensive traits into single individuals should substantially reduce the likelihood that herbivores will become resistant. Thus, theory in evolutionary ecology has contributed concrete strategies that could greatly enhance the “longevity” of plant defenses, with enormous economic consequences.

Synthesis

Of the numerous specific concepts and theories discussed in this article, some general ideas emerge that relate pattern to process and dynamics to structure. First, complicated spatial or temporal patterns in population densities do NOT require environmental explanations or complicated underlying dynamics—rather, we should expect patterning, cycling, and complexity simply because of the feedbacks inherent in ecological systems. This is of more than theoretical interest, because it implies that any management of ecological systems must heed the implications of nonlinear dynamics. In other words, we must anticipate that rates of change in population growth or in number of species may change dramatically and suddenly, not just because of random fluctuations in the environment, but also as a result of deterministic processes. Second, several ecological models, including epidemiological and meta-population models, point to critical thresholds across which systems change qualitatively (e.g., a disease can no longer persist, or a population dwindles toward extinction because colonizations fail to balance local extinctions). Third, opportunities for coexistence of species arise whenever the world in which organisms live becomes less uniform—spatial heterogeneity creates refugia, disturbances interrupt the process of competitive exclusion, and so on. In contrast, human actions tend to enforce regularity and control on the natural world, and ecological theory suggests that this homogenization of nature is contributing to the erosion of our planet's biodiversity. The consequence of this reduction in biodiversity remains an open theoretical question, with the greatest

challenges to ecological theory being the development of models that contend with rich webs of species interactions in complex ecosystems. The future of ecological theory lies in blending human activities with natural processes, so that we can better understand how to encourage a sustainable biosphere while accommodating human interests and demands.

Glossary

Ecosystem services The wide array of benefits that ecosystems, and their biodiversity, confer on humanity.

Marginal value The economic value of the next incremental unit of something. In this context, marginal values are those associated with managing the next small unit of an ecosystem in a particular way (e.g., preserving, rather than clearing, the next unit of forest). They can also be the partial contribution of natural capital to a final good that is produced with other inputs. For example, the marginal value of irrigation water for crop production is the value of the incremental crop yield that

can be attributed to irrigation, rather than to labor, fertilizer inputs, etc.

Natural capital Here we focus on living, renewable forms of natural capital, which constitute a stock – of an ecosystem and the biota that makes it up – that generates a flow of ecosystem services. For example, a forest constitutes a stock that generates a flow of timber, carbon sequestration, water quality, biodiversity, serenity, and other benefits, depending upon how it is managed. (Fossil fuels and other minerals constitute non-living natural capital, which is generally non-renewable on time scales of interest to society.)

Introduction

Ecosystem services are essential to sustaining and fulfilling human life, and yet their supply is seriously threatened by the intensification of human impacts on the environment. This article provides an overview of issues concerning the identification, biophysical and economic characterization, and safeguarding of ecosystem services.

Over the past decade, efforts to value and protect ecosystem services have been promoted by many as the last best hope for making conservation mainstream – attractive and commonplace worldwide. In theory, if institutions recognize the values of Nature, then we can greatly enhance investments in conservation and foster human well-being at the same time. In practice, scientific and policy communities have not yet developed the scientific basis or the policy and finance mechanisms for integrating natural capital into resource and land-use decisions on a large scale. Here we describe the history, progress, and key frontiers for advancing the science and practice of accounting for natural capital in the decisions of individuals, communities, corporations, and governments.

What are Ecosystem Services?

Definition and Classification

Ecosystem services are defined simply as the benefits that people obtain from ecosystems (MA, 2005). They sustain and fulfill human life and flow from many conditions and processes of ecosystems, and the species making them up (Daily, 1997). The processes and features generating ecosystem services (ES) are so tightly interconnected that any classification is inherently somewhat arbitrary. The most widely used

classification was developed through the Millennium Ecosystem Assessment (MA) and identifies four classes of ES based on their types of benefits to society:

1. *provisioning services* including the production of goods such as food, water, timber, and fiber;
2. *regulating services* that stabilize climate, moderate risk of flooding and disease, and protect or enhance water quality;
3. *cultural services* that provide recreational, esthetic, educational, community, and spiritual opportunities; and
4. *supporting services* that underlie provision of the other three classes of benefits, including soil formation, photosynthesis, nutrient cycling, and the preservation of options (Figure 1; MA, 2005).

The classification of ES is still a topic of debate and several other classification approaches have been suggested (e.g., De Groot *et al.*, 2002).

The ecosystem services framework is system- and scale-neutral, applying equally to terrestrial, freshwater and marine ecosystems and their processes, anywhere on the spectrum from relatively pristine to heavily managed conditions. Indeed, all ecosystems provide, to differing degrees, a set of ES. Human conversion of ecosystems from one type to another is often motivated by a desire for a different set of ES, though consideration of the services of the two systems and their tradeoffs is often incomplete.

Ecosystem Services Across Systems

In the terrestrial realm, croplands, natural and managed forests, grasslands, and wetlands can provide a wide range of ES. In each of these systems, for example, vegetation can protect and enhance soils, preventing their loss through erosion and

Washington, DC: Island Press, with permission from World Resources Institute.

improving fertility by retaining moisture and storing and recycling nutrients. Vegetation and soils together regulate the quantity, quality, and timing of water flows, thus moderating floods and droughts and providing cleaner, more reliable supplies.

Forests stand out as important in regulating water and carbon cycles in their strong influence on local, regional and global climate and because of the multiple, interacting threats to their future. They also provide natural products for subsistence use or sale including timber, firewood, mushrooms, fruits and seeds, medicinal plants, rubber, cork, and bushmeat. Forest and woodland habitats harbor species that provide pollination and pest control to commercial or subsistence crops. Grassland and other dryland systems play these same critical roles in addition to supporting vast livestock populations (MA, 2005). Wetlands occupy a small fraction of Earth's surface, but dominate the landscape where they are concentrated and provide a wide array of water quality, flood mitigation, coastal protection, and biogeochemical services (MA, 2005). Each of these systems, however natural or managed, can provide habitat for biodiversity and opportunities for recreational activities, spiritual experiences, and creative, cultural expression.

Freshwater ecosystems provide a suite of highly visible and widely appreciated ES. The freshwater regulated by terrestrial

systems and the atmosphere is used for drinking, hydropower production, irrigation, household activities (washing etc.), industrial purposes (cooling, manufacturing, etc.), and cultural experiences. People also gain large revenues and nutrition from freshwater fisheries and aquaculture. Less appreciated is the value of sediment transport and deposition in rivers that supply river reaches and downstream beaches with important sand and gravel resources. Wetlands and other aquatic vegetation can regulate flood waters and cycle nutrients, improving water quality. Finally, freshwater systems serve as pathways for human transportation and recreational or cultural activities.

Marine ecosystems also provide all four classes of ecosystem services described in the MA. Marine fisheries and aquaculture provide nutrition, feed for animals, livelihoods and important recreational and cultural opportunities. Harvests of other species for food additives, cosmetics, and pharmaceuticals also support health, nutrition, and livelihoods. Marine biogenic habitats (such as coral reefs, oyster reefs, and kelp forests) regulate natural hazards including storm surges, and may play a critical role in helping coastal communities adapt to sea level rise. Marine systems also transform, detoxify, and sequester wastes. In addition, oceans are the center of the global water cycle; they hold 96.5% of the earth's water and are a primary driver of the atmosphere's

temperature, moisture content, and stability. Oceans are also key players in the global cycles of carbon, nitrogen, oxygen, phosphorus, sulfur, and other major elements and are responsible for approximately 40% of global net primary productivity. Finally, coastal communities reap many benefits from coastal tourism (one of the world's most profitable industries), and numerous coastal communities define their very identities in relation to the sea and all it brings.

The Ecosystem Service Supply Chain

All of these services flow to people along a supply chain from biophysical systems to people (Tallis *et al.*, 2012). All services are generated by some function or element of a natural or managed system (Figure 2). The full suite of these elements or functions can best be considered in three discrete steps: Supply, service, and value. For example, consider protection from coastal storm surges. Many different types of coastal elements (e.g., coral reefs, mangroves, oyster beds, barrier islands) confer protection from storm surges by attenuating waves. The full set of locations of these coastal elements represents the supply of protection from storms. People do not receive storm surge protection from all of these locations, however, because some are far from human infrastructure and settlement. Both the distribution of human infrastructure and settlement, together with the location and condition of supply, are required to give a clear picture of how much "service" is actually delivered at a given time. Finally, the service delivered to human communities is often valued differently, depending on the context. For example, coastal protection services provided by nearshore habitats to easily accessible, popular, public

beaches might be seen as more valuable than those to more remote sites.

History of the Concept of Ecosystem Services

The nature and value of ecosystem services have been illuminated primarily through their disruption and loss. For instance, deforestation has demonstrated the critical role of forests in the hydrological cycle – in particular, in mitigating floods, droughts, the erosive forces of wind and rain, and the silting of dams and irrigation canals. Release of toxic substances, whether accidental or deliberate, has revealed the nature and value of physical and chemical processes, governed in part by a diversity of microorganisms, that disperse and break down hazardous materials. Thinning of the stratospheric ozone layer sharpened awareness of the value of its service in screening out harmful ultraviolet radiation. And the loss of coastal wetlands has brought into relief their importance in regulating coastal hazards such as hurricanes and tsunamis.

Initial Development of the Ecosystem Services Concept

A cognizance of ecosystem services, expressed in terms of their loss, dates back at least to Plato and probably much earlier:

What now remains of the formerly rich land is like the skeleton of a sick man with all the fat and soft earth having wasted away and only the bare framework remaining. Formerly, many of the mountains were arable. The plains that were full of rich soil are now marshes. Hills that were once covered with forests and produced abundant pasture now produce only food for bees. Once the land was enriched by yearly rains, which were not lost, as they are now, by flowing from the bare land into the sea. The soil was deep, it absorbed and kept the water..., and the water that soaked into the hills fed springs and running streams everywhere. Now the abandoned shrines at spots where formerly there were springs attest that our description of the land is true. (– Plato)

Figure 2 Three measurement points for ecosystem services (Reproduced from Tallis H, Lester SE, Ruckelshaus M, *et al.* (2012) New metrics for managing and sustaining the ocean's bounty. *Marine Policy* 36: 303–306.). Supply metrics deal only with the biophysical system underpinning the service of interest. Service metrics include critical information linking supply to beneficiaries. Value metrics weight the level of service based on people's preferences or social policy goals.

Mooney and Ehrlich (1997) trace modern concern for ecosystem services to George Perkins Marsh, a lawyer, politician, and scholar. Indeed, his 1864 book *Man and Nature* describes a wide array of services, again, often expressed in terms of their loss. Remarking on the terrain of the former Roman Empire, he notes that it "is either deserted by civilized man and surrendered to hopeless desolation, or at least greatly reduced in both productiveness and population" (p. 9). He goes on to describe the reduction of hydrological services: "Vast forests have disappeared from mountain spurs and ridges, the vegetable earth ... [is] washed away; meadows, once fertilized by irrigation, are waste and unproductive, because ... the springs that fed them dried up; rivers famous in history and song have shrunk to humble brooklets" (p. 9). He also made connections between deforestation and climate: "With the disappearance of the forest, all is changed. At one season, the earth parts with its warmth by radiation to an open sky – receives, at another, an immoderate heat from the unobstructed rays of the sun. Hence the climate becomes excessive, and the soil is alternately parched by the fervors of summer, and seared by the rigors of winter. Bleak winds sweep unresisted over its

surface, drift away the snow that sheltered it from the frost, and dry up its scanty moisture" (p. 186). Finally, he even wrote of decomposition services: "The carnivorous, and often the herbivorous insects render an important service to man by consuming dead and decaying animal and vegetable matter, the decomposition of which would otherwise fill the air with effluvia noxious to health" (p. 95).

Following World War II, other eloquent writers on the environment emerged, including Fairfield Osborn (*Our Plundered Planet*, 1948), William Vogt (*Road to Survival*, 1948), and Aldo Leopold (*A Sand County Almanac and Sketches from Here and There*, 1949). Each discusses ecosystem services without using the term explicitly. In *The Population Bomb* (1968), Paul Ehrlich describes anthropogenic disruption of ecosystems and the societal consequences of doing so, addressing the need to maintain important aspects of ecosystem functioning. Along these lines, the *Study of Critical Environmental Problems* (1970) presents a list of key "environmental services" that would decline with a decline in "ecosystem function." This list was expanded on by Holdren and Ehrlich (1974). Meanwhile, in the 1960s and 1970s, economists set out to measure "the value of services that natural areas provide," with efforts focused on agricultural production and environmental amenities.

By the early 1980s, efforts were initiated to investigate two questions: The extent to which ecosystem function (and the delivery of services) depends on biodiversity, and the extent to which technological substitutes could replace ecosystem services. The first question is addressed in Biodiversity and Ecosystem Services in this volume. The second question was tackled by Ehrlich and Mooney (1983). Work on these topics proliferated and, in 1997, a collective effort was made to synthesize the wealth of scientific information that had accumulated on the functioning of ecosystem services, with a preliminary exploration of their economic value, and of key issues meriting further work (Daily, 1997).

Recent Advances

Four major advances of the last decade have revitalized research on ecosystem services and brought them into the public eye. First, the MA represented a visionary and seminal step in global science – it was the first comprehensive global assessment of the status and trends of all of the world's major ecosystem services. It was requested by United Nations Secretary General Kofi Annan in 2000 and carried out between 2001 and 2005 with contributions from more than 1360 experts worldwide. The key finding of this assessment was that two-thirds of the world's ecosystem services were declining (MA, 2005). This captured the attention of world leaders and emphasized the connections between human decisions and the natural environment that feedback to the human condition via changes in the flow of ecosystem services.

Work following the MA clarified this chain of connections (Figure 3) (Daily et al., 2009). Human decisions shape individuals' actions relating to the use of land, water, oceans, and other elements of natural capital. These actions often alter the state or functioning of ecosystems, which in turn provide altered flows of benefits (goods or services) to people. People express different values (monetary, cultural) associated with

Figure 3 A framework showing key elements for integrating ES into decision-making (reproduced from Daily GC, Polasky S, Goldstein J, et al. (2009) Ecosystem services in decision-making: Time to deliver. *Frontiers in Ecology in Ecology and the Environment* 7: 21–28). One could link any two ovals, in any direction, in different decision contexts.

these altered streams of benefits and it is the expression of these values that leads to changes in institutions that guide decisions. The following three recent advances all concern the connections in this flow.

We have recently seen large advances in our understanding of the links between ecosystem functions and processes and the provision of ecosystem services (Figure 3). For some ecosystem services, we now better understand the key ecological system components that drive provision and we can now measure and model, with uncertainty, the impacts of land use and resource management decisions on a wider variety of ecosystem processes and associated services. Ecological science has also advanced spatially explicit modeling, which is essential for mapping ecosystem services and their flows to people (e.g., Chan et al., 2006). Finally, we are starting to see patterns in how multiple ecosystem services and biodiversity change in relation to each other. Recent work has started characterizing bundles of ecosystem services, and exploring their synergies and tradeoffs (e.g., Bennett et al., 2009).

Further, economic valuation methods have been applied to the spatial provision of ecosystem services to estimate the monetary value of benefits and, in some cases, the distribution of those benefits to various segments of society (NRC, 2005). In addition, qualitative and quantitative methods from other social sciences have been applied to gain better understanding of the social and cultural importance of ecosystem services (e.g., MA, 2005).

Lastly, experiments in payments for ecosystem services in ecosystem-based management and in regional planning have begun, giving us opportunities to learn about how science can play a role in altering institutions, and how institutions alter decisions and the resulting flow of ecosystem services. The following section describes some of these efforts in more detail.

Incorporating Ecosystem Services into Decisions

The urgent challenge today is to move from theory to practical implementation of ES tools and approaches in resource decisions taken by individuals, communities, corporations, and

governments. The framework in **Figure 3** connects the science of quantifying services with valuation and policy to devise payment schemes and management actions that take account of ecosystem services. This connection is expressed in the real world in a variety of ways across scales from local to global.

Over the past decade, a great number and diversity of efforts to implement the ES framework have emerged worldwide. Individually, most of these efforts are small and idiosyncratic. But collectively, they represent a powerful shift in the focus of conservation organizations and governments (primarily) toward a more inclusive, integrated, and effective set of strategies. Taken together, these efforts span the globe and target a full suite of ecosystem services, including principally forest-generated services of carbon sequestration, water supply, flood control, biodiversity conservation, and enhancement of scenic beauty (and associated recreation/tourism values).

Many local or regional ES efforts focus on a single service that stands out as sufficiently important, from economic and political perspectives, to overcome the activation energy required to protect it. Under the institutional umbrella created for the focal service, it is possible that other services may be at least partially protected. Beginning in the late 1990s, large-scale investment in natural capital for water flow regulation in China – and for a broad suite of ES in Costa Rica – set pioneering examples that are now being adapted elsewhere and scaled up.

The brief summaries offered next illustrate several models of success at different scales and in different kinds of social-ecological systems. In each case, there is an acute or looming crisis, innovative leadership, and pursuit of dual goals: Improving both human and ES condition.

Local Scale: Water Funds

New York City made one of the first and most famous investments in ecosystem service provision in recent history, in the mid-1990s. The city invested *ca.* US\$1.5 billion in a variety of watershed protection activities to improve drinking water quality for 10 million users rather than spending the estimated US\$6–8 billion needed (excluding annual operating and maintenance costs) for building a new filtration plant. This seminal example is widely cited as evidence of the business case for investing in natural capital instead of built capital. Yet the effort remains very much an experiment in the science and policy of investing in natural capital, and one on which there is international focus.

Globally, watersheds are now emerging as the target of a range of creative policy and finance mechanisms that link beneficiaries to suppliers through a payment system. In these “water funds,” water users voluntarily pay into a pool that is collectively managed by contributors and invested in watershed management improvements. The Nature Conservancy (TNC) has now established more than 10 water funds in Latin America, has plans to create 22 more by 2015 and is exploring the possibility of establishing the first funds in Africa.

One of the established water funds, *Agua por la Vida y la Sostenibilidad*, demonstrates the diversity of water users that are becoming engaged in these funds and the kinds of

watershed management changes these funds motivate. Formally established in the Cauca Valley, Colombia in 2009, this water fund is supported by the region’s sugar cane grower’s association (PROCAÑA), the sugar producers’ association (ASOCAÑA), 11 local watershed management groups, TNC and a Colombian peace and justice nongovernment organization. Each member of the water fund voluntarily pays a self-determined amount into the fund that is then jointly managed by the members to improve landscape management in 11 watersheds covering over 3900 km².

Members in this fund have currently committed to contributing US\$10 million over 5 years to be invested in five kinds of management changes: Protection of native vegetation, restoration of denuded lands, enrichment of degraded forests, fencing of rangelands, and implementation of silvo-pastoral practices. The fund is starting a monitoring program that will ensure that these investments lead to measurable improvements in water quality for approximately 1 million water users downstream and significant improvements in terrestrial and freshwater biodiversity.

Local Scale: Coastal and Marine Spatial Planning

People have historically thought of oceans as relatively featureless expanses that defy the drawing of lines on maps. However, recent political and scientific advances have highlighted the need for a comprehensive approach to planning marine and coastal uses and the need for practical tools to make this more comprehensive approach a reality on the ground and in the water. In a marine spatial plan, a wide range of uses of the marine environment are put on one map. But an understanding of how such plans are likely to yield changes in the delivery of the broad range of services people receive from the system has, until recently, remained elusive.

Along the west coast of Vancouver Island Canada, multiple, often competing interests are struggling to define the future character of the place. Existing extractive, industrial, and commercial uses; traditional First Nations subsistence and ceremonial uses; recreation and tourism; and emerging ocean uses such as the extraction of wave energy are all in the mix. The West Coast Aquatic Management Board (WCA) is charged with creating a marine spatial plan for the region. WCA is a public–private partnership with participation from four levels of government (Federal, Provincial, local, and First Nations), and diverse stakeholders. Ultimately, WCA’s vision is to manage resources for the benefit of current and future generations of people and nonhuman species and communities.

Some key pillars of the partnership’s strategy are to: use a precautionary, ecosystem-based approach to protect, maintain, and restore marine and coastal resources; respect and protect First Nations’ food, social and ceremonial requirements and treaty obligations; integrate expertise and knowledge from First Nations, local, scientific, and other sources; ensure broad participation in the planning process; and foster initiatives that maintain or enhance opportunities for coastal communities to benefit from local resources, while achieving sustainable social, cultural, and economic benefits for the region. WCA has partnered with the Natural Capital Project to

explore how alternative spatial plans might affect a wide range of ES and to provide information about tradeoffs among ES.

Some key considerations for WCA and their stakeholders include balancing important industrial and commercial activities (such as shipping, mining, logging, aquaculture, and fisheries), increased development of tourism and recreation, renewable energy generation, and a strong cultural desire for sustaining the remote, wild feeling of the place. WCA is exploring the suitability of alternative regions for these different activities. For example, maps of coastal vulnerability to erosion and flooding from storm surge are helping to direct coastal development permits to low-risk areas. Similar maps of the value of captured wave energy are being overlaid with existing ocean uses (e.g., fishing and recreational activities) to highlight regions of high wave energy value, where wave energy generation facilities might be constructed while having minimal impacts on other activities. Examinations of tradeoffs among aquaculture (finfish, shellfish), wild salmon fisheries, recreation (e.g., kayaking, whale watching, and diving), coastal development (on the coast, as well as floathomes), and habitat and water quality are underway.

The general framework of ES and ES modeling, in particular, are helping to articulate connections between human activities that are often considered in isolation, to align diverse stakeholders around common goals, and to make implicit decisions explicit. ES modeling results have informed early iterations of the marine spatial plan and will inform the creation of the final plan in 2012.

National Scale: Land-Use Planning and Human Development in China

The ecosystem service investments being made in China today are impressive in their goals, scale, duration, and innovation. Following massive droughts and flooding in 1997–1998, China implemented several national forestry and conservation initiatives, into which investments exceeded 700 billion yuan (*ca.* USD100 billion) over 2000–2010 (Liu *et al.*, 2008). The larger and older of these initiatives are being rigorously evaluated to determine their biophysical and socioeconomic impacts, to improve their design and efficacy.

These initiatives have dual goals: To secure critical natural capital through targeted investments across landscapes and regions, and to alleviate poverty through targeted wealth transfers from coastal provinces to inland regions where many ES originate. The Chinese government aims to reduce the loss of soil, improve water retention, reduce desertification, and generally protect biodiversity and ecosystems in the west of the country for flood control, hydropower production efficiency, irrigation supply, more productive agriculture, and ecotourism. In addition, it wants to change the economic structure in rural areas to increase local household income while simultaneously making local households' patterns of land utilization and agricultural production more sustainable (Liu *et al.*, 2008).

The initiatives include two national PES programs, the Natural Forest Conservation Program (NFCP) and the Sloping Land Conversion Program (SLCP), established in 1998 and 1999, respectively. Implementation was tested in a few

provinces, and then rapidly scaled to the whole country. Evaluation of the programs shows significant achievement of the biophysical goals, with remarkably rapid land conversion in the desired directions. For example, by the end of 2006, the SLCP had converted *ca.* 9 million hectares of cropland into forest/grassland and had afforested *ca.* 12 million ha of barren land. Village level field measurements have shown not only that the payments for ES have altered land-use patterns, but in turn soil erosion has been decreased in some areas by as much as 68% (Cao *et al.*, 2009).

Overall social impacts of the programs are mixed. In some places, payment levels and types are leading to improvements in economic measures of well-being, whereas in others payments were not sufficient to compensate for loss of income from shifting livelihoods (Liu *et al.*, 2008). In addition, in some places where participation in the SLCP has significant positive impacts on household income, it has not yet transferred labor toward nonfarming activities as the government wished. Payments are now being adjusted to improve success in achieving goals of poverty alleviation and growth of new economic sectors in rural areas.

China is also now in the process of establishing a new network of Ecosystem Function Conservation Areas (EFCAs), specifically for ES provision. Their exact delineation is now being determined through quantitative ecosystem service mapping and valuation. They are expected to span *ca.* 25% of the country.

The current and potential future impacts of ES investments in China are enormous, certainly within the country – and also globally, in the form of enhanced carbon sequestration and reduced dust export, and perhaps most importantly in lessons on making the investments needed in natural capital and human well-being everywhere.

International Scale: Global Policy and Research Efforts

As described above, the MA was the first major effort to establish ES in the international policy arena. Activities stemming from that effort are now aimed at bringing countries together in making tangible commitments to safeguard ES (e.g., 2020 targets for the Convention on Biodiversity) and to assess national and international progress toward those commitments (e.g., through Group on Earth Observations Biodiversity Observation Network (GEO BON) and the Programme on Ecosystem Change and Society (PECS), which synthesize knowledge for the International Platform for Biodiversity and Ecosystem Services (IPBES), formally established in 2010). Several new international research efforts aim to feed into these international processes, including the Natural Capital Project, The Resilience Alliance, and the Stockholm Resilience Centre. Other entities are focused on establishing and tracking ES markets, as one mechanism for bringing larger attention to ES benefits to society (e.g., The Katoomba Group and The Ecosystem Marketplace, both initiated by Forest Trends). As one example of many burgeoning international efforts, we describe in greater detail the Natural Capital Project.

The Natural Capital Project (NatCap) (www.naturalcapitalproject.org) is an international partnership working to align economic forces with conservation, by developing tools that

Figure 4 An iterative process for integrating ecosystem services into decisions. The process begins with stakeholder engagement around impending decisions, with a focus on realistic, alternative scenarios for the future. The modeling is shaped by stakeholders, and typically focused on the services and scenarios deemed most important. Outputs are displayed in accordance with stakeholder preferences, in the form of maps, tradeoff curves, and/or balance sheets. These can be expressed in biophysical (e.g., tons of carbon), economic (e.g., dollars), or cultural (e.g., visitor-days) terms. Reproduced from Daily GC, Polasky S, Goldstein J, *et al.* (2009) Ecosystem services in decision-making: Time to deliver. *Frontiers in Ecology and the Environment* 7: 21–28.

make incorporating natural capital into decisions easy and replicable; by demonstrating the power of these tools in important, contrasting places; and by engaging leaders globally. NatCap is developing InVEST, a family of tools for Integrated Valuation of Ecosystem Services and Tradeoffs.

InVEST helps decision makers visualize the impacts of potential policies by modeling and mapping the delivery, distribution, and economic value of ES under alternative scenarios. The outputs identify tradeoffs and compatibilities between environmental, economic, and social benefits. InVEST is designed for use as part of an active decision-making process (Figure 4) and can be applied at local, regional, or global scales. The first phase of the approach involves working with stakeholders to identify critical management decisions and to develop scenarios that project how the provision of services might change in response to those decisions as well as to changing climate, population, etc. Based on these scenarios, a modular set of models quantifies and maps ES. The outputs of these models provide decision makers with information about costs, benefits, tradeoffs, and synergies of alternative investments in ES provision.

NatCap is using InVEST in major natural resource decisions in diverse contexts around the world, including in the three examples given above (water funds, coastal and marine spatial planning, and land-use planning and human development in China). The aim is to demonstrate the power of these approaches and to learn how to replicate and scale up models of success. The Project is engaged in a suite of international efforts, including GEO BON and IPBES, to offer a common, unifying platform for regional and national efforts that are spawned by these initiatives.

Outstanding Challenges

With the rapid rate of development of ES mapping, from the biophysical and economic modeling through to policy application in diverse socioeconomic contexts, it is likely that great advances will be made in coming years. What we report here is only a beginning. There are key arenas in which further learning is crucial to understand what drives variation in the provision of ES, how they percolate through various arms of society and how social reaction leads to sustainable or unsustainable change in ES provision.

Relating Ecosystem Services and Human Health

The relationships between biophysical attributes of ecosystems and human health are complex. Destruction of natural ecosystems can at times improve aspects of public health. Draining swamps, for example, can reduce habitat for the mosquito vector that transmits the parasite that causes malaria. However, destruction of other systems can have sharp negative consequences for human health. There is emerging evidence that loss of tropical forests, for example, leads to an increase in transmission of malaria (Patz and Olson, 2006). Similarly, fragmentation of, and biodiversity loss from, eastern North American forests is associated with an increase in lyme disease (Keesing *et al.*, 2010). Natural and managed ecosystems provide many services that sustain human health, through provision of human nutrition (especially of protein and micronutrients); purification and regulation of drinking water; regulation of air quality; regulation of vector-borne disease; and psychological benefits. There is a great need for research illuminating the links between biodiversity, ecosystem conditions and processes, and human health.

Tradeoffs and Synergies

The relationship between ES and biodiversity and among different ES varies with socio-ecological context. In some cases, clear tradeoffs and synergies among services have been defined in specific contexts, but there is still much to be learned about what determines the nature of these relationships. Advancing this knowledge is essential because policies addressing management change can only be successful if management controls ES relationships. If policies are established to align multiple ecosystem services, but biophysical conditions in the system lead to innate tradeoffs among services, management changes are bound to fail in delivering the desired improvements to social benefits.

Distributional Effects

Much of the science of mapping ES has focused on identifying where ES are generated and where they are delivered. However, less work has focused on identifying to whom ES actually flow. This connection is essential if policies addressing ES delivery are to be equitable and either improve the well-being of the poor or avoid unintended distributional consequences. Past work in this arena has focused on overlaying maps of ES provision with an array of poverty indicators. Missing from this spatial analysis

is information on access to and ability to control the delivery of ES. In many cases (e.g., for services such as clean drinking water, hydropower production, agriculture, water for irrigation, wave power generation), the actual delivery of services to specific people is affected by the location of infrastructure or institutions regulating access to resources. New science is needed that allows the ready mapping of these connections and the prediction of how they will change under future conditions.

Dynamic Effects – and Shocks and Uncertainty

Dynamic changes, such as in climate and in the nitrogen cycle – as well as changes arising through economic development and evolving human preferences over time – are very important. The possibility of feedbacks within ecosystems, and between ES and human behavior, is a key area for further development. Feedback effects can give rise to thresholds and rapid changes in systems that can fundamentally alter system outcomes. The ability to incorporate shocks and the possibility of surprises is another area where further development is needed. Fires, droughts, and disease all can have major influences on ecosystems and affect the services produced. Changes in economic conditions or fads in human behavior can similarly cause major changes in systems (e.g., financial crises). The occurrence of each of these and other potential disturbances is difficult to predict but virtually certain to come about. Understanding their likely impacts on ecological and social systems will help us prepare for them.

Valuation in Monetary and Non-Monetary Terms for Decision-Making

Monetary valuation of ES is not nearly as prevalent as sometimes assumed. More typically, real-world applications of the ES framework rely on biophysical values to inform policy design, such as measures of water quality or flood risk.

Value is not always easily characterized or fully captured in monetary terms, so it is important to characterize value in multiple dimensions, including health, livelihood support, cultural significance, etc. (e.g., Dasgupta, 2001). This will help ensure that valuation and broader decision-making approaches are inclusive of the range of benefits and people concerned. Interdisciplinary efforts are presently underway to create a conceptual framework that is useful both in theory and in practice for a broad suite of cultural ES.

Institutional Design

However ES are measured, there is a need for political and social science research to design institutions and mechanisms that better capture externalities. Efforts such as national accounts are blossoming now, but it is unclear how they will evolve and how successful governments will be at incorporating natural capital into national measures of wealth. There is great work to be done in determining the merits and limitations of alternative policy and finance mechanisms, in different economic, governance, and other social contexts (e.g., Ostrom, 2005). There is also great work to be done in

developing institutions that achieve representation and participation by stakeholders as part of adaptive governance systems (e.g., Cowling *et al.*, 2008).

Conclusions

Ecosystem services have had a relatively long history through indirect recognition of the importance of nature for the persistence of the human endeavor. There are scientific challenges for biogeochemists, hydrologists, ecologists, economists, political scientists, epidemiologists, anthropologists, and other social scientists to understand how human actions affect ecosystems, the provision of ES and the value of those services. At least as demanding are the social and political questions associated with incorporating this understanding into decision-making. There is also a need to design effective and enduring institutions to manage, monitor, and provide incentives that reflect the social values of ecosystem services. Information is becoming more readily available for individuals, corporate managers, and government officials who make decisions affecting ecosystems and their services to consider a more complete set of costs and benefits associated with their choices. We are likely to see continuing growth in our scientific ability to measure and predict changes in ES, our ability to design policies and institutions that accurately represent these changes and in turn, the ability of the environment to continue providing the many benefits society needs to prosper.

Glossary

Adaptive syndrome A coordinated set of adaptations.

Community An assemblage of populations that coexist in an area.

Eltonian niche The role, or occupation, of a species in a community.

Exploitative competition An adverse interaction which results from organisms depleting their shared resources.

Family A category, in the classification of evolutionary lineages, of related organisms that ranks above a genus and below an order. A family usually contains many genera.

Grinnellian niche The requirements and behaviors expressed by a species wherever it normally occurs.

Hutchinsonian niche The set of environmental conditions, or opportunities, that will permit a species to exist indefinitely. The set of opportunities that are available to a guild can be referred to as a “nook.”

Individualism of species Refers to the observation that the distributions and abilities of most species do not exactly coincide because each species is the product of a unique evolutionary history. Coevolution and convergence may occur, but rarely are these processes so complete that groups of species are distributed as a unit or superorganism.

Taxon A general term used to indicate groups of related organisms at any level in a taxonomic hierarchy. In the classification of evolutionary lineages, the term can refer to species, genera, families, orders, etc.

The Definition and Properties of Guilds

Guilds are groups of species that exploit the same class of resources in a similar way (Root, 1967). This simple definition has several implications that are best explained by way of an example. Consider the birds that probe for insect prey on the bark of tree trunks (Figures 1 and 2). In many parts of North America this guild is composed of small woodpeckers (family Picidae), nuthatches (family Sittidae), and treecreepers (family Certhiidae). The guild also contains the black-and-white warbler (family Parulidae), whose relatives are primarily adapted for gleaning insects from foliage. Guilds thus contain species with very different phylogenetic histories and, as a consequence, with different propensities for dealing with the special requirements associated with exploiting a particular resource. Thus, the woodpeckers and treecreepers have evolved stiffened tails to act as props in climbing tree trunks, whereas the nuthatches and warbler have evolved modifications of the foot to assist in moving on vertical surfaces.

In addition to the core members of the guild which take the bulk of their food by foraging on trunks and limbs, there are many species, such as titmice (family Paridae), that occasionally feed by probing bark. The presence of these infrequent bark probers illustrates that guilds can have a hierarchical structure with members that range from strict specialists to occasional opportunists. As a consequence, the size and makeup of the guild will depend on where we draw the line with respect to the proportion of a species' diet that is obtained while probing bark.

The hierarchical structure of guilds is also reflected in how broadly we interpret the “in a similar way” portion of the definition. For instance, there are ants that forage for insect prey on tree trunks. These insects have the potential of influencing the food supply available to the bark probers. Their

foraging style, however, is fundamentally different: Ants rely on their small size to enter bark crevices, whereas the birds employ their relatively large mass to lever out embedded prey and to flake bark. In this example, it can be seen that the scope of a guild's delimitation needs to be matched to the question being asked. The broader definition, which includes ants, might be most useful if our primary concern is competition, and the narrower concept, which excludes ants, might be more appropriate if our primary interest is in the evolution of adaptations. Furthermore, the birds eat the ants, which introduces further complications if the ants are lumped into the same guild with the birds.

During the northern winter, the black-and-white warbler migrates to the American tropics, where it joins another representation of the bark-probing guild which includes the tropical woodcreepers (family Dendrocolaptidae) and barbtails (family Furnariidae) shown in Figure 2. The warbler's experience illustrates that guild membership can vary in space and season.

The opportunities provided by the existence of bark-dwelling arthropods, many of which are in a cryptic resting stage, has been exploited by bark probers that evolved from several phylogenetic lineages throughout the world. Thus, the Australian manifestation of the bark-probing guild contains Australasian treecreepers (family Climacteridae) and sittellas (recently placed in their own family, the Neosittidae). On Madagascar, the bark-probing role is filled by the nuthatch-vanga (family Vangidae), and on the Galapagos Islands the woodpecker finch (family Fringillidae) uses cactus spines to probe for prey under bark.

In classifying the ways that organisms exploit resources, guilds hold a rank that is similar to genera in phylogenetic schemes. One may also think of a guild as a group of species that occupy similar niches. Indeed, one of the original

Figure 1 A few members of the bark-probing guild in North America.

motivations for introducing the guild concept was to clarify confusion regarding the niche concept, which was used to describe three quite different entities: (i) the Hutchinsonian niche, which refers to the set of conditions that are sufficient for a species to exist in a particular habitat; (ii) the Grinnellian niche, which refers to the requirements and behaviors that are expressed wherever a species normally occurs; and (iii) the Eltonian niche, which refers to the role or occupation of a species in a community. The Eltonian niche was usually viewed as a relatively broad category (e.g., sap-feeding insects and predators of small mammals) which could contain several species and occur in a variety of habitats. In creating the guild concept, we provide an alternative category which clarifies some of the ambiguities associated with the Eltonian niche. For instance, by substituting guild for the Eltonian niche, we can avoid the contradictions that occur when several similar species are said to occupy the same "niche," a category that is supposed to be a property of individual species according to the Hutchinsonian and Grinnellian concepts. Accordingly, species exploit niches and guilds exploit "nooks"—the adaptive space that is presented by resources with similar characteristics.

There are many types of guilds in addition to those that are based on food resources. For instance, animals can be grouped according to their use of tree cavities for nest sites and plants

Figure 2 Birds from different regions and lineages that have independently evolved the bark-probing habit. The dendrocolapids and furnariids live in the American tropics and the climacterids and neosittids live in Australia. The woodpecker finch is one of the Darwin's finches that inhabit the Galapagos Islands.

can be grouped according to their shared use of agents for pollination (e.g., moths or hummingbirds) and seed dispersal (e.g., fruit-eating birds or wind). In the case of plant-eating insects, there has been a tendency to define "mixed" guilds that group species according to a combination of overlapping functions. Frequently, the "feeding guild," defined on the basis of the insects' mode of feeding and the plant tissues they ingest, is combined with the "sheltering guild," defined on the basis of the insects' use of different plant structures as lairs for protection from enemies and adverse conditions. As a result, we often find that plant-chewing insects are divided into categories such as "leaf-miners," "leaf-rollers," "shoot-borers," and "stem galls" that have been shaped by the interaction of nutritional and protective functions. In searching for patterns, it is important to take all these mixed functions into full account.

It should also be kept in mind that species can belong to more than one guild. For instance, the woodpeckers

mentioned previously are members of both the feeding guild that probes bark and the nesting guild that utilizes tree cavities. Many insects shift from one guild to another during the course of development because larvae and adults are adapted to perform such different functions. Thus, most butterfly species have caterpillars that are in the leaf-chewing guild and adults that are in the nectar-drinking guild.

The Utility of Guilds in the Search for Organization and Patterns

Guilds Provide a Natural Unit of Manageable size for Comparative and Evolutionary Studies of Species Interactions

Even fairly simple communities, such as old fields in the temperate zone, can harbor more than 1500 species of insects belonging to more than 175 families. Such diversity obscures our view of fundamental processes, such as competition, mutualism, and evolution, because most species interact only rarely. This requires that we sort out the insignificant interactions to appreciate the true intensity of the critical interactions. For instance, most species of plant-eating insects in an old field rarely come into direct contact with one another because they are adapted for feeding on different plant species. As a consequence, the use of standard sampling methods, such as sweeping vegetation with a net or collecting the moths that are attracted to lights, which combine the insects on different plant species, would blur our understanding of competitive interactions between plant feeders. Furthermore, the existence of many types of species presents technical difficulties. Thus, to measure the density of all the plant feeders in a community might involve censusing deer, rabbits, mice, sparrows, snails, grasshoppers, caterpillars, aphids, galls, and tiny mites. Clearly, each of these categories of plant feeders require somewhat different methods based on different assumptions, relating to different spatial scales, and having different biases. To avoid these difficulties, ecologists often restrict their attention to some portion of the community. The guild concept is ideally suited to this purpose.

In defining a guild, we create a community detachment whose members share resources that are exploited in a similar way. In many situations, guilds have an advantage over partitioning on the basis of taxonomy because the members of a taxon may be utilizing a variety of resources in a variety of ways. For instance, a bird community may contain rodent-eating owls and seed-eating sparrows but take no account of rodent-eating weasels and seed-eating mice. This is not to imply that guilds are necessarily invalid if all their members are drawn from the same major taxon; frequently, certain styles of exploiting resources are only “available” to organisms with capabilities that evolved in particular taxa. As discussed previously, birds possess the beak and body mass required to probe tree bark. Focusing on a guild has the added advantage of improving our ability to conduct accurate censuses on all the guild members because by sharing the same resources they are likely to be found in the same microhabitats and, by behaving in a similar way, they are more likely to have similar reactions to being observed or captured. Furthermore, the

resources, by virtue of belonging to the same class, can be more accurately measured and compared. As a consequence, we are in a position to draw closer comparisons and conduct more realistic experiments when we are working with a guild.

By observing how a guild changes along spatial gradients, we can seek patterns in the relationships between environmental factors and variations in population density, reproductive rate, body size, dispersal ability, investment in predator or herbivore defenses, and a variety of other traits within a group of species that are comparable because they use similar resources in a similar way. Such comparisons also permit us to examine how species are “packed” onto the guild’s resource base in relation to disturbance, elevation, and latitude.

Comparisons of similar guilds can reveal interesting patterns. For instance, there is a much smaller range of sizes of plant-chewing insects that live in abodes, such as mines and leaf rolls, compared to that of plant chewers that feed in exposed locations. This pattern reflects the limitations on body size that are imposed by the small spaces provided by plant structures that are pliant enough to be penetrated or rolled.

Much can be learned by comparing the same guild in regions that have been isolated from one another so that their biotas have undergone independent evolution (Figures 1 and 2). In such comparisons, the discovery of close resemblance provides insights into the process of convergent evolution. In particular, we can observe (i) if certain types of characters are more responsive to evolutionary pressures, (ii) if certain combinations of traits are associated with each other in different regions, and (iii) the degree to which convergence is limited by deep ancestral traits in the various phylogenetic lines that make up the guild.

Guilds Partition Biotas into Entities Appropriate for Detecting Community Organization

Ecologists have long debated the significance of exploitative competition in organizing communities. An important line of inquiry in this debate concerns the constancy of a community’s functional relationships. The reasoning is as follows: If communities are competitively organized, we expect to find that important functional relationships are predictable in space and time because the waxing and waning of populations of one species would be countered by compensatory changes in the populations of other species that use the same resource. Furthermore, these compensatory responses are expected to be most intense within groups of species that have similar methods of using the shared resources. Finally, we might expect to find that similar types of communities have similar functional profiles because the imperatives associated with using similar resources have sorted and shaped species into convergent groups. Guilds provide a means of partitioning a community into functional entities in which these compensations might be detected.

Much of the search for community organization has focused on plant–insect associations. One reason for doing this is that the basic resources (the biomass of foliage, stems, roots, flowers, and seeds produced by a particular plant taxon) are well circumscribed and relatively easy to measure. The

constancy of the association's functional profile can be judged by changes in the guild spectrum—the proportion of total herbivore biomass that is engaged in exploiting different plant parts in various ways. A matrix for sorting insect herbivores into guilds is presented in **Table 1**. In all likelihood, such a scheme will need to be revised to suit the needs of a particular investigation.

Evidence for community organization based on guilds has been elusive. For instance, Cornell and Kahn found extensive variation in the guild spectra associated with 28 tree species in Great Britain and Root and Cappuccino found no evidence for compensatory changes in the densities of species within guilds that feed on goldenrods. These failures draw us to question our assumption that the intensity of competition is likely to be most severe within guilds. Different types of resources are linked in nature. Thus, in plant–insect associations, the consumption of leaves will reduce the future availability of seeds and the sapping of juices from stems will reduce the nutritional quality of foliage eaten by leaf chewers. Similarly, the caterpillar eaten by a foliage-gleaning bird is unavailable as a moth to bats that forage in the air. Linked resources link guilds and open the possibility for exploitative competition to play out its effects across a diffuse network of species. In other words, the use of a common resource seems to be of primary importance in competitive interactions; the manner in which the resource is exploited is of little consequence unless differences in a guild's behavior permit members to use an exclusive subset of resources. As a consequence, there are many cases of competition between guilds. For example, Schluter found that Darwin's finches in the Galapagos Archipelago consumed more nectar on islands on which nectar-feeding carpenter bees were absent.

Of course, competition could be operating in a diffuse fashion that would be difficult to detect by only studying variations in guild spectra. In plant–insect associations, however, there is increasing evidence from long-term experiments and extensive surveys that plants in natural communities are rarely devastated by herbivores and that competition between plant-eating insects is a sporadic occurrence. These results, considered in conjunction with the highly variable guild spectra that have been reported by Cornell, Root, and Strong, suggest that most plants could support more herbivore species (i.e., plants provide Hutchinsonian niches that have not been filled) and that the structure of these associations is idiosyncratic, largely determined by the characteristics of a few dominant species that happen, for a variety of historical reasons, to have evolved to become members of the community.

Many ecologists have the impression that guilds and communities that are dominated by predators or vertebrates are more likely to be organized by competition and to exhibit more predictable functional profiles. This impression, however, has not been adequately evaluated.

Guilds Provide a Framework for Describing and Comparing the Trophic Structure of Ecosystems

The trophic structure of ecosystems is often described in terms of broadly defined levels consisting of primary producers, primary and secondary consumers, decomposers, and so on. Food webs, on the other hand, are described in terms of individual species. Various attempts have been made to develop a scheme based on guilds that can be used to describe trophic structure with an intermediate degree of refinement; thus, herbivores might be subdivided into browsers of woody plants, grazers of grasses, sap-tappers on succulent foliage, borers in stems, and so on. To accomplish this requires that the entire community be partitioned so that all its members can be placed into a standard set of feeding guilds that have a widespread occurrence in nature. When ordered in this way, it is hoped that insights about energy flows can be gained by drawing comparisons between systems. In practice, however, such schemes have been little used, probably because it is almost impossible to develop a “key” to the guilds of the world that is flexible enough to accommodate a wide array of taxa and yet sufficiently circumscribed that different ecologists will assign species to guilds in the same manner.

The Individualistic Nature of Species and the Vague Boundaries of Ecological Categories

The process of defining guilds raises some fundamental questions. Are guilds distinct entities that reflect the outcome of natural processes or are they merely artificial groupings that we invent to divide diversity into more comprehensible units? In other words, are the opportunities provided by the environment discontinuous so that species are sorted into clearly defined groups on the basis of their requirements and lifestyles? Furthermore, are similar openings (or nooks) available in different regions? Are organisms constrained from filling these opportunities by their evolutionary histories? We can begin to address these difficult questions by comparing the characteristics of the core and marginal members of various guilds.

Table 1 A Provisional matrix for defining guilds of insects that feed on terrestrial plants

<i>Manner of feeding</i>	<i>Resource</i>							
	<i>Buds and leaves</i>	<i>Pliant stems</i>	<i>Flowers</i>	<i>Pollen</i>	<i>Fruits</i>	<i>Seeds</i>	<i>Wood and bark</i>	<i>Crusts of algae, molds, etc.</i>
Chewers								
Exposed	✓	✓	✓	✓	✓	✓		✓
Concealed	✓	✓	✓		✓		✓	
Sap-tappers	✓	✓	✓		✓	✓		
Gall-makers	✓	✓	✓		✓			
Grazers				✓				✓

If we census the habits of all the species that utilize a particular resource, we usually find that there is a wide variation in the level of their dependency on the resource. The most dependent species—the core users—usually possess obvious specializations. Thus, in the bark-probing guild (Figure 1), the treecreepers, woodpeckers, and nuthatches, which take the bulk of their diet from bark, have specialized feet and tails for moving on vertical surfaces (Richardson, 1942). In our census, however, we usually encounter a host of species that use the resource only rarely. These marginal users are either generalists or they are specialized along other lines that compromise their ability to use the resource in question. For instance, bark-probing titmice often forage on horizontal surfaces, such as the tops of limbs and branches, where they take much of their prey by hammering apart acorns, galls, and similar objects that they hold against the perch with their foot. These habits are reflected in the distinctive foraging maneuvers that titmice display during their infrequent forays onto tree trunks. Other species, such as gnatcatchers, vireos, and wood warblers, which are primarily adapted for gleaning insects from tree foliage, make clumsy efforts to take insects from bark on rare occasions.

Here we confront the individualistic nature of species—a fundamental issue, originally raised by Gleason, that complicates all of our efforts to define functional groups of species. Thus, the various taxa that can utilize a particular resource have evolved “individualistically” along independent paths. As a result of their separate histories, these taxa have different constraints and proclivities, which result in different levels and styles of specialization. As a consequence, guilds often have ambiguous boundaries consisting of several species of generalists and inept opportunists that are specialists on other resources. Since the degrees of dependency grade into one another, the line one draws to define the membership in a guild can be somewhat arbitrary.

The indefinite boundaries of guilds are merely one expression of a more general issue confronting ecologists. Community ecology and biogeography are, by their very nature, concerned with levels of organization that consist of multiple species. In their efforts to discover the processes operating at these levels, workers have developed several systems for classifying species into groups on the basis of similarities in their (i) response to physical or site conditions to define communities; (ii) possession of particular adaptive traits to define life-forms and adaptive syndromes; (iii) response to seasonal cues to define phenological aspects; (iv) geographic distributions to define biogeographic provinces, biomes, life zones, and plant formations; and (v) diet to define trophic levels. Ecologists recognize and discuss these entities because they find that several species fall into clusters on the basis of these various types of classification. As with guilds, however, we also encounter species with intermediate characteristics that tend to blur the boundaries of these various categories. This is because all the traits that underlie these classifications are subject to the same individualistic evolution that can produce the marginal members of a guild. Thus, vague boundaries are an inherent property of any species assemblage—a fact that requires ecologists to cultivate certain habits of mind in forming arguments.

Attitudes Concerning Vaguely Bounded Categories

People are generally uneasy about categories, such as guilds, that are subjectively defined because the criteria one chooses to define the operational boundaries will have an impact on our ability to observe patterns. Thus, if a guild is defined too broadly, the characteristics of a miscellaneous collection of marginal species could obscure interesting similarities between the core members. On the other hand, if a guild is defined too narrowly, we could overlook the full range of influences that stem from extracting a particular resource in similar ways. There have been a variety of attempts to address this problem by using quantitative procedures, such as cluster analysis and principal components analysis, to delimit the membership in guilds. The raw material for these analyses comes from “activity censuses” which measure the relative frequency that species utilize different resources in different ways. The groupings that are sorted out by these procedures, however, often seem abstract and artificial. Furthermore, they are probably no less arbitrary than those that are more subjectively defined because the person who is running the analysis must decide how broadly to cluster the species’ activities.

Despite these difficulties, the continued and widespread use of subjectively defined categories attests to the need of such concepts in ecology. The best results are obtained when we follow some simple guidelines. In the case of guilds, the classifications that provide the most insights are based on a thorough knowledge of the species’ natural history. Open-minded observations and journal keeping are good starting points to form an intuition for distinguishing resources with properties that require special means for their efficient exploitation. For instance, insects on bark constitute an appropriate resource for a guild of bird-sized predators because the core members must move on vertical surfaces and extract prey from narrow crevices or under bark—maneuvers that are difficult for birds that lack the necessary specializations.

After a guild has been tentatively defined, it helps to conduct activity censuses at different sites and in different seasons to discipline intuition and provide a quantitative basis for determining guild membership. (For sedentary organisms such as plants, one would count the incidence of the traits that define the guild along transects laid out in appropriate habitats.) When the investigators are satisfied that a guild “makes sense” with respect to the questions that are being asked, the criteria that will be used to delimit the boundaries should be clearly described and fully justified. At this point, it may be useful to assign classes of membership; for instance, core species might be those that engage in the activities that define the guild on at least 50% of occasions, and marginal or accidental species might be those that engage in such activities on less than 10% of occasions. Many of these steps seem obvious, but they are often left out of guild classifications, especially in cases in which the investigators are attempting to partition entire communities in such a way that each species can be assigned to a single guild. Such classifications are often used to compare the functional organization of communities in which only the most general of categories can accommodate the great diversity of species that must be placed.

Part of the art of becoming an ecologist involves developing a set of attitudes for coping with the complications

that stem from the individualistic nature of species. One of the most important of these is an ability to match the question one is asking with the most appropriate grouping of species—the set that will reveal valid patterns that act in nature. Thus, the guild definition that is most useful for exploring convergent evolution may be quite different from the one that is best for observing compensatory shifts in the densities of interspecific competitors. In addition, we need to be on steady guard against the natural tendency to drift into thinking that the entities we have invented are “real.” Guilds are not a fixed feature of nature. They are a convenience that we can use to cope with diversity, reveal patterns, and facilitate discussion. As a consequence, guilds can be modified as long as they provide a valid base for addressing a question and their limits are explicitly defined and justified.

Glossary

Adaptive radiation Evolution of ecological and phenotypic diversity within a rapidly multiplying lineage.

Allopatric Occurring in separate, nonoverlapping geographic areas.

Dioecious In plants, having the male and female reproductive organs borne on separate individuals of the same species.

Disharmony The nonrandom representation of biota among natural colonists of oceanic islands as compared with mainland systems. Species that are more dispersive will have a higher representation in the biota, the effect being accentuated by the tendency of these few successful colonists to diversify into multiple species through adaptive radiation.

Ecomorph A local population or group associated with a particular ecological niche; the term has no systematic or taxonomic significance.

Endemic/endemism Unique to a given locale; occurs in the site at which it is endemic, and nowhere else.

Impoverishment On an island, paucity of species relative to adjacent mainland.

Invasional meltdown The compounded effect on an ecological community of successful and successive

invasions of alien species benefiting from the previous introduction of the other.

Microcosm A small, representative system that has analogies to a larger system. Oceanic islands are often considered microcosms of continental areas because the composition of species on islands, and the processes of formation and decline, are analogous but occur on a very small scale.

Parapatric Occurring in geographical areas that abut but do not overlap.

Phylogenetics The study of evolutionary relatedness among various groups of organisms (e.g., species and populations). Phylogenetics, also known as phylogenetic systematics, treats a species as a group of lineage-connected individuals over time.

Relictualization Survival of species on islands after those on adjacent mainland areas have suffered extinction.

Sympatric Occurring in the same geographic areas without interbreeding.

Taxon cycle A hypothesis proposed by E. O. Wilson to describe the common niche expansion among colonizers, and subsequent long term toward differentiation, with isolated species narrowing their niches and restricting their ranges resulting in eventual extinction.

Introduction

There is a huge diversity of types of islands, but the common denominator is that they are isolated, well-defined geographically, and have distinct boundaries. These characteristics can result in properties such as of a microcosmal nature and a uniquely evolved biota. Indeed, the flora and fauna of oceanic islands inspired scientific interest from the moment explorers first began sailing the oceans. The importance of evolutionary processes on islands was first recognized in Charles Darwin's work on the Galapagos, which gave rise to the theory of evolution by means of natural selection. Likewise, Alfred Russell Wallace contemporaneously developed similar theories based on studies in the Spice Islands of Indonesia. Over the last century, research has focused on multiple facets of islands—from the mechanism of formation of the isolated habitat and how its geological history has been shaped, to the colonization of species and the development of uniquely evolved biotas in similarly unique communities and ecosystems (Keast and Miller, 1996). Island ecosystems tend to be simple when compared with continental ecosystems; thus, the way ecosystems function can be more easily studied. In essence, islands can be considered as Nature's test tubes. Each island represents a trial in an

experiment and each new island is the repeat of one of these experiments.

Islands can be broadly classified as one of the two types, continental or oceanic. Continental islands are fragments of a larger landmass, often created by a rise in sea level or when land breaks off and drifts from the mainland. Oceanic islands (e.g., [Figure 1](#)) can result from volcanoes rising above the water on or near a mid-ocean ridge, or where lithospheric plates converge (Nunn, 1994). The key biological difference between a continental and an oceanic island is that the former, when created, has a full complement of species (or at least a sample of what occurred on the continent before the fragment became isolated), and the number of species, at least initially, will tend to decline as a result of stochastic events. In contrast, oceanic islands are formed without life, so the number of species can only increase, and will do so at a rate that will depend on the interplay of isolation and time (Gillespie and Roderick, 2002). If the islands are not extremely isolated, equilibrium will be reached between immigration of colonists and extinction. With greater isolation (and lower immigration rates), and given sufficient topographical diversity, local endemism will increase over time. Extreme isolation, with the frequency of colonization being insufficient to allow the occupation of available ecological niche space

Rotui, Moorea (Society Island archipelago, French Polynesia) showing topographical diversity characteristic of younger volcanic islands; higher elevation forested habitat is shown in the foreground. (b) Atoll in Micronesia. Such oceanic islands, which show little topographic diversity, harbor relatively few terrestrial species, with little endemism. Photos by G.K. Roderick and R.G. Gillespie.

through migration, can provide the opportunity for adaptive radiation, and has been called the “radiation zone” (Whittaker, 1998). Here, species diversity arises through the formation of multiple new species adapted to exploit the available ecological space.

Over the last few years, geological understanding of islands has improved immensely. For many oceanic archipelagoes, the age of each island is often known with some level of precision. This, coupled with the fact that diversification on these islands has a clearly recognizable beginning (colonization from outside), has given biologists a temporal framework within which to examine ecological and evolutionary processes, and the formation of communities over time.

Characteristics of Biodiversity

Community Characteristics

Disharmony

On oceanic islands, the biota is often considered to be “disharmonic.” This phenomenon arises partly because taxa differ considerably in their ability to colonize remote islands, leading to attenuation in the number of groups represented on more isolated islands. Moreover, as a consequence of the isolation, islands generally show a degree of impoverishment when compared with continental communities. Adaptive radiation accentuates this effect, with multiple species arising from the few that successfully colonize, the result being very

few families and genera compared with overall diversity. This pattern has been noted in the Canary Islands, (Juan *et al.*, 2000) but the effect is particularly well illustrated as one crosses the Pacific Ocean from west to east in the direction of increasing isolation of an oceanic island (Figure 2; it should be noted that this figure excludes continental islands such as New Caledonia and New Zealand, in which ancient connections to continental landmasses also appear to have allowed high levels of endemism).

Endemism

The pattern of species accumulation on oceanic islands depends on the rate of evolution relative to the frequency of island colonization, the extreme cases leading to extensive adaptive radiation as a result of *in situ* evolution with associated adaptation to occupy the available ecological space. On remote islands, the frequency of colonization becomes vanishingly rare. As a result, the biodiversity of remote islands has largely arisen through evolution and adaptation of the few initial colonists, and levels of endemism are consequently very high (see Table 1 for a comparison of endemism among different groups of species in the Canary, Galapagos, and Hawaiian islands). The effect of isolation on endemism is shown in Figure 2, which illustrates how endemism increases with isolation in the oceanic islands of the Pacific.

Relictualism

The mainland taxa that give rise to the island colonists exist in an environment that is often very different from that of

species on islands. Accordingly, species that colonize islands may suffer extinction, though this cannot generally be distinguished from the effects of disharmony. Likewise, island progenitors may become extinct on the mainland yet remain extant on islands, because competition may not be as severe, the climate is less extreme; in this case the species on the islands can be considered “relicts.” Clearly, this effect will be much more pronounced on older islands or archipelagoes.

Species Characteristics

Reduced Dispersal Capabilities

Loss of dispersal ability is a common feature of taxa on oceanic islands (Williamson, 1981). The phenomenon was first documented by Darwin, who suggested that “powers of flight would be injurious to insects inhabiting a confined locality, and expose them to be blown to the sea.” For example, island plants are renowned for their large seed size and associated loss of dispersal ability. Among endemic/indigenous

Table 1 Approximate levels of endemism (%) for different groups of native organisms on three of the better-known oceanic archipelagoes

	Birds (all species)	Flowering plants	Terrestrial invertebrates
Canary Islands	45	40	58
Galapagos Islands	48	36	50
Hawaiian Islands	81	91	98

Figure 2 Plant transect across selected Pacific islands: indigenous species, area, and endemism. Larger islands have disproportionately larger numbers of species, as documented in MacArthur and Wilson (1967)’s “*Equilibrium Theory of Island Biogeography*.” The initial idea of equilibrium numbers of species on islands was based on a balance between immigration (decreases with distance from a source of colonists) and extinction (decreases with island size). However, the high levels of endemism on remote islands also reflects the role of evolution within these islands, which may compensate for low levels of immigration with numerous species arising through adaptive radiation.

insects, 90% of those on Tristan de Cunha and 40% on Campbell Island show some degree of wing reduction. Among birds, flightlessness has evolved repeatedly on islands where predators are absent. Such reduction in dispersal ability may accelerate species diversification. However, many of the flightless birds on islands have been driven to extinction as human occupation spread, for example, in Hawaii the flightless rails and geese and the large flightless waterfowl the moa nalos, in Mauritius the Dodo, and in Madagascar the elephant bird.

Innovations

The known disharmony of islands appears to stimulate the development of some unusual traits in island groups. For example, Hawaiian birds have developed a remarkable diversity of elongate and decurved bill shapes, presumably because of the availability of nectar resources. The Hawaiian silver-sword plant alliance includes trees, shrubs, subshrubs, rosette plants, cushion plants, and a vine, that occur in some of the wettest sites recorded on Earth to extreme desert-like environments. Among insects, the absence of native social insects in some of the more remote islands of the Pacific may have been largely responsible for the adaptive shift to predation in some terrestrial insect groups and the diversity of other predatory arthropods on these islands. One of the most striking innovations is the development of predatory behavior in a lineage of Hawaiian caterpillar moths in the genus *Eupithecia* (Howarth and Mull, 1992). Another innovation in Hawaii has been the development of odonate damselflies with terrestrial larvae, associated with the paucity of lakes in the upland yet moist forests of the islands. Similarly, the unusual habitat of cryptogram herbivory in beetles in the subantarctic islands is considered to be a result of the disharmony of the flora.

Size Changes

Species on islands show a tendency toward size extremes, both gigantism and dwarfism. Overall, among mammal species that colonize islands, large species tend to get smaller while small ones tend to get larger. Included among the islands' giants are the giant flightless birds of New Zealand (moa) and Hawaii, giant sheet-web spiders of the remote Pacific islands, and hissing cockroaches of Madagascar. Dwarf species include elephants, foxes, rabbits, and snakes as well as the pygmy mammoth, which once inhabited California's Channel Islands. It appears that size changes are associated with the very different conditions experienced by island species, often with fewer constraints on size extremes.

Reproductive Changes

A common pattern seen in plants that colonize islands is the development of dioecy, asexual reproduction, and low rates of reproduction, each of which may arise as a result of selection for loss of dispersal ability, together with high selfing rates, after lineages have become established on remote islands. The Hawaiian Islands, for example, are particularly rich in dioecious species with about 15% dioecy in native species of flowering plants (compared with 6% in mainland species).

Island Dynamics

Colonization

Given a suitable abiotic environment, the success of any given colonization event depends largely on the availability of ecological space, although chance clearly plays a role. The importance of available ecological space is clearly illustrated on isolated archipelagoes that are formed serially, some in a linear fashion as they emanate from an oceanic hotspot. There is generally a heavy bias in the direction of more recent colonization toward younger islands (Wagner and Funk, 1995), which suggests that, once ecological space is "filled" on these islands, there is little further colonization.

Species Change Subsequent to Colonization

What happens to a population subsequent to successful colonization? Initially, the population may change ecologically, but over time evolutionary changes occur.

Ecological Change

Subsequent to the initial establishment of species in new habitats, a common outcome is ecological (or competitive) release, with colonizers expanding their range to fill the available ecological space. Regular cycles of distributional change following colonization of islands have been proposed several times in the literature, starting with the idea suggested by E. O. Wilson for a "taxon cycle" in Melanesian ants: widespread, dispersive populations give rise to many more restricted and specialized populations or species (Wilson, 1961). Although the generality of the taxon cycle has been questioned, the tendency for species to expand their range to fill the available ecological space upon initial colonization of an area is quite predictable.

Evolutionary Change

As described above, the remoteness of many oceanic islands allows evolution to play a prominent role in the addition of species to such islands, and adaptive radiation of species from single colonizers is a frequent characteristic of the more remote archipelagoes. Mechanisms underlying adaptive radiation on oceanic islands have been the subject of considerable interest ever since Darwin described the radiation of finches in the Galapagos (Grant, 1986). However, the extreme diversity of form and modifications associated with island colonization, coupled with the superficially similar appearances of many species on different islands within an archipelago, made it very difficult to understand how, and from where and what the diversity had arisen. The advent of molecular genetic methods has led to a huge growth in research on oceanic islands and has allowed the evolutionary history of organisms to be assessed (Givnish and Sytsma, 1997). Given the microcosmic nature of islands, with a finite pool of colonizers, and the diversification of these into multiple closely related species confined to small areas, knowledge of the evolutionary history of the biotas has allowed some profound insights into the mechanics of population divergence, and the interplay between isolation, sexual selection, and ecological shifts in allowing species formation.

Adaptive radiation, by definition, involves ecological diversification (Schluter, 2000). On oceanic islands, ecological isolation is clearly demonstrated by numerous sympatric members of an adaptive radiation. Within a radiation of long-jawed spiny-legged spiders in the Hawaiian Islands, 5–8 species co-occur at a given site, each species ecologically distinct from the others with which it co-occurs. Likewise, among the Hawaiian honeycreepers, seven ecologically distinct species co-occur at a single location in high-elevation forests on the island of Hawaii. The ecological differences among species are often profound, particularly on more remote islands where a given lineage can sometimes monopolize the ecological arena that would be used by multiple genera, families, or even orders, in continental areas.

Adaptive radiation is frequently associated with an acceleration in rate of diversification. However, the rate of diversification within an adaptive radiation may be further enhanced by sexual selection. Recent research has shown that crickets in the Hawaiian Islands have the highest documented rate of speciation known, which has been attributed to the role of courtship or sexual behavior in accelerating species divergence (Mendelson and Shaw, 2005). Likewise, sexual selection is thought to have played a prominent role in the diversification of Hawaiian drosophilid fruit flies (Kaneshiro and Boake, 1987), leading to the large number of native species (~800 in two genera, *Drosophila* and *Scaptomyza*) (Carson and Kaneshiro, 1976).

The initial processes of divergence leading to species formation on oceanic islands is still not entirely understood, particularly with respect to the relative importance of allopatric, parapatric, and sympatric speciation. Adaptive shifts clearly underlie species diversification in many radiations of species in isolated islands, although separation of gene pools is generally considered to be a requirement in initiating the process and has been demonstrated in the initial diversification of finches in the Galapagos, beetles in the Canary Islands, and spiders in the Hawaiian Islands, among other groups. In each case, subsequent sympatry appears to have led to ecological differentiation. In the Hawaiian Islands, differentiation among marginal isolates or founder populations appears to have been involved in species formation within radiations of *Drosophila* and carabid beetles. Parapatric divergence through adaptive shifts may have played a role in the initial divergence of cave-adapted species and has been implicated in the formation of cave endemics from surface relatives in the different Hawaiian Islands (lycosid spiders and isopods) and the Canary Islands (dysderid spiders) (Roderick and Gillespie, 1998). The idea that species on islands may be able to diverge in sympatry held considerable popularity for many years, but increasing evidence from phylogenetic studies has provided little support to the idea. Cases where multiple sister species co-occur within a single island are most commonly found in arthropods, and may be attributed to parapatric or “micro-allopatric” speciation, although some authors have suggested that sympatric speciation may have played a role in the diversification of palms on Lord Howe Island (Savolainen *et al.*, 2006) and lineage of tiny weevils (genus *Miocalles*) on the single small island of Rapa in southern French Polynesia. Together, these studies show that whatever the mechanism allowing initial divergence of

populations, ecological segregation clearly plays the primary role in allowing coexistence of close relatives of an adaptive radiation.

Species Diversification

Species and the communities in which they live are dynamic entities, their existence, distribution, and abundance, dictated by evolutionary and ecological responses to both natural and anthropogenic environmental change. For hotspot archipelagoes—those in which islands emanate from a single volcanic hotspot from which they progressively move away—afford a unique opportunity: they make it possible to visualize snapshots of evolutionary history. For example, the geological history of the Hawaiian archipelago is well understood, with individual islands arranged linearly by age (Figure 3), allowing early stages of diversification and community formation to be studied on the island of Hawaii and compared with progressively later stages on the older islands of Maui, Lanai, Molokai, Oahu, and Kauai (Roderick and Gillespie, 1998). A similar chronological arrangement is found in the archipelagoes of both the Marquesas and the Societies in French Polynesia. Because of this geological history, coupled with their extreme isolation, the Pacific hotspot archipelagoes afford the opportunity for phylogenetic study of community formation within a temporal context. Other hotspot archipelagoes, such as the Galapagos and the Canary Islands, show temporal variation although islands in these groups are arranged as a cluster rather than a linear series, yet on these islands also the evolutionary progression of species tends to be from older to younger islands, and it may be possible to use the history of these islands in the same way as that in hotspot islands, to examine stages in adaptive radiation and community formation.

Extinction

Species on islands tend to have a limited geographic distribution and the naturally small population sizes means that most of these populations will not suffer additional inbreeding depression. However, they are vulnerable to extinction as a result of demographic stochasticity. Accordingly, natural extinction rates on islands are expected to be high. In the tropical islands of the Pacific, extinction has been much higher than on the islands of the north Atlantic, where species ranges are much broader. The naturally small population sizes and ranges make island species more vulnerable to extinction as a result of natural competition or habitat degradation due to geological and climatic changes, and such effects have played a pivotal role in shaping island biotas. At the same time, these same attributes of island species makes them more vulnerable to human-mediated impacts (see below).

Processes of Community Formation

Over the last few years, studies have started to incorporate phylogenetic history into the investigation of community assembly (Losos, 1992). While most of these studies argue for

Figure 3 Major hotspot archipelagos in the Pacific. The archipelagos of the Hawaiian Islands, Marquesas, and Society Islands are shown on the map of the Pacific, with approximate geological ages of each island indicated. Within each archipelago, the oldest island is to the northwest, the youngest to the southeast.

the nonrandom nature of community composition, they have demonstrated opposing forces in shaping communities. For example, habitat filtering in which only taxa with certain traits colonize a community, can lead to phylogenetic clustering within that community. However, competitive exclusion, in which taxa that exploit similar resources will compete and exclude each other, can lead to phylogenetic overdispersion (Figure 4). Oceanic islands have played a key role in the integration of phylogenetics and evolutionary biology into studies of community composition. Using the fact that a given island system often includes multiple co-occurring representatives of the same lineage it is possible to infer how characters have changed to allow multiple

species to co-occur in a community. In general, such studies have highlighted the role of convergent evolution, and suggest that community formation is somewhat deterministic. Accordingly, in a radiation of Hawaiian *Tetragnatha* spiders, ecologically and morphologically similar sets of species (ecomorphs) occur in most habitats on all islands: one "green spiny," one "large brown spiny," one "maroon spiny," and one "small brown spiny." These sets of species appear to have arrived in a habitat, either by direct colonization from an older island, or by evolution of one ecomorph from another on the same island, suggesting convergence of the same set of ecological forms on each island (Gillespie, 2004).

Figure 4 Hypothetical scenario of phylogenetic relationships among spiders showing how different ecological forces give rise to opposite expectations about the similarity of species traits within communities. Phylogenetic clustering may occur if closely related species share similar physiological limitations; similar adaptations allow species with similar traits to co-occur in the same habitat. Phylogenetic overdispersion may occur as a result of competitive exclusion among related species preventing coexistence of close relatives that share a resource, leading to ecological divergence among close relatives.

Species Loss

While the isolation of oceanic islands has made them living laboratories for understanding species adaptation and evolution, it has also made them extremely vulnerable to invasive species and other stresses. The vulnerability of islands to extinction is now widely recognized. Islands have suffered much higher rates of extinction than continents (Steadman, 1995). Of approximately 100 known land bird species in the Hawaiian Islands, almost 75% of the species present at first human contact have disappeared completely and many of those that survive are in danger of extinction (James, 1995). The situation is similar for native plants, in which about 120 of 1000 flowering species have fewer than 20 individuals left in the wild, and Hawaii has lost more documented arthropod species than the entire continental United States. Indeed, the Hawaiian Islands have been dubbed the “extinction capital of the world.” Given the information on species diversification that scientists have been able to determine from oceanic islands, can we also use the islands as tools to understand human-mediated extinction? Extinction is clearly more gradual in continents than on many islands, but the trajectory is similar. Accordingly, understanding of the processes involved in species extinction in the islands, and replacement of largely native environments by species from elsewhere, may allow the development of effective conservation strategies in mainland habitats.

Alien Species Invasion

One of the most severe impacts affecting many island systems comes from nonnative species (Sax *et al.*, 2005). For insects,

extinctions attributed to alien species invasion have been noted on Guam and the Galapagos. However, perhaps because it is the most remote archipelago, alien species in Hawaii appear to have taken a much greater toll on the native biota. The numbers now estimated for organisms purposely or accidentally introduced into Hawaii and established are 3046 arthropods, 20 reptiles, 46 land birds, 19 mammals, and 927 plants.

Community dynamics, and the ability of invasive species to penetrate certain native communities, and of certain native communities to withstand invasion, has been the subject of numerous articles (Stone and Scott, 1985). However, extensive research over the past few decades has shown that multiple parameters may act (or interact) to dictate invasion success, the most common being: (i) species diversity itself has been found, under some conditions, to serve as an ecological barrier to invasion; this effect has been used to explain the higher frequency and impact of invasions on islands which are considered to be relatively species poor; (ii) disturbance and the opening of ecological space can facilitate invasion; (iii) propagule pressure, in particular the relative abundance of native versus nonnative propagules, can permit infiltration of alien species into native habitats; (iv) characteristics of propagules, such as more generalist habitat requirements, can affect invasion success; and (v) novelty of perturbations and “naïveté” of native biota can accentuate the impact of an invasive species.

It is widely cited that the worst kind of introduction to an isolated archipelago is that of a generalist predator or competitor capable of exploiting a broad array of habitats and causing secondary impacts. This can sometimes result in an effect known as “invasional meltdown.” For example, the crazy

ant *Anoplolepis gracilipes* has invaded Christmas Island, resulting in complete modification of the ecosystem in just 2 years. Supercolonies of the ants extirpate the dominant native omnivore, a large land crab, which in turn leads to increased seedling recruitment but slows litter decomposition. At the same time, the association of the ants with plant-feeding insects increases the abundance of Homoptera, with associated increased impacts on plants including honeydew productions, which in turn enhances sooty moulds.

Devastating introductions by generalist predators/competitors such as pigs are largely (though by no means completely) historical, occurring before protocols were established for the introduction of nonnative species. However, abundant, small human commensals, such as ants (Figure 5), mosquitoes, and agricultural and horticultural pests, are continually expanding their range on to oceanic islands. Moreover, although the introduction of highly specialized species for biocontrol purposes has been believed to be safe in that they are unlikely to go beyond the confines of their specialized host or habitat, evidence is accumulating in Hawaii to suggest that specialized species can expand their range when faced with novel conditions, and may do so quite dramatically.

Demographic Effects—Small Population Sizes

The limited geographic range and small population sizes that characterize islands make them vulnerable to demographic stochasticity (see above). Species with naturally small population sizes are similarly more vulnerable to habitat modification, simply because loss of even a small amount of habitat for a geographically restricted species could easily reduce numbers below sustainable levels.

Abiotic Effects—Climate Change

Islands can also be highly climate-sensitive. In the past two decades, for example, short-term extreme high temperatures contributed to a decline of coral reefs throughout the tropics. Corals, stressed by high temperatures, may eject their symbiotic algae resulting in coral bleaching, which renders the corals vulnerable to any further physiological stress and many of the colonies die. In 1994, elevated sea temperatures killed over 90% of the living corals of American Samoa from the intertidal zone to a depth of 10 m and fishing catches declined drastically following the coral death. Likewise, during the El Niño of 1997–98, coral bleaching in Palau, known for its spectacular coral reefs, was extensive.

Other concerns of climate change relate to the fact that most of the island species have restricted distributions such that local vagaries of climate can eliminate species so restricted as compared with more widespread taxa. In particular, the high-elevation cloud forests that characterize many oceanic islands have a narrow geographical and climatological niche that may be eliminated with even a slight climatological change. Climate change may also precipitate declines in forests due to floods, droughts, or increased incidence of pests, pathogens, or fire. In addition, increases in the frequency or intensity of hurricanes may cause disturbance that favors invasive species.

Sea level rise is also a concern for oceanic islands, resulting in coastal erosion and salt water intrusion into freshwater lenses. However, it is the low-lying islands and atolls that are the most vulnerable from these effects.

The Future of Biodiversity on Oceanic Islands

Oceanic islands have served as a source of intrigue for biologists for centuries. Not only are they discrete units within which the biota can be quantified and compared, but the interplay of isolation and time has allowed the development of uniquely derived faunas on some islands. Understanding of the interplay between time and isolation in allowing these unique sets of biota to develop is still limited. Even more limited is our knowledge of the nebulous concept of “vacant niche space,” which appears to play a critical role in fostering colonization and diversification. There is much to be learned from the natural patterns of diversification on islands. At the same time, the current rate of anthropogenically induced habitat degradation and homogenization of the world’s fauna threatens the biota of the world, particularly that of islands. So what are the priorities for addressing the ongoing extinction crises on these islands?

Taxonomic Knowledge

On many islands, the taxonomic impediment is huge. Accordingly, determining the status of a species, whether it is native or not, remains a major challenge for a conservation biologist on oceanic islands, particularly for those working on arthropods or other megadiverse groups. This problem is especially acute in tropical areas where knowledge of both potentially native and the pool of nonnative species is frequently sparse and unreliable. Research is needed to determine the identity and distribution of native and alien species on different islands, and subsequently to determine their evolutionary history and assess their future trajectory.

Development of Realistic Evolutionary Trajectories

In a world subject to accelerating global and local environmental change, policy makers and planners are struggling to maintain the status quo of diversity in natural systems. At the same time, there is growing appreciation that biological diversity is inherently dynamic. Conservation strategies that do not incorporate these evolutionary and ecological dynamics and that ignore the spatial flux in environmental quality will inevitably fail. Accordingly, an explicitly dynamic approach is required to allow the assessment of the conditions under which areas of endemism are either sensitive or resilient to environmental change. Oceanic islands provide circumscribed areas of discrete, highly endemic, assemblages of organisms within which understanding of evolutionary and ecological dynamics shaping the biota is an achievable goal.

It is not clear what such an assessment will tell us. For example, considering the Hawaiian Islands, it is estimated that the existing angiosperm flora developed from 265 colonization events (not including introductions or doubtfully native taxa),

Figure 5 Invasion of the little fire ant, *Wasmannia auropunctata*, in the Pacific. *W. auropunctata* is native to South and Central America. Over the last century, the species has invaded multiple locations worldwide, and in each location its invasion has been associated with substantial impacts on the native biota. (Note that lower green represents New Caledonia and higher green the Solomons; similarly 1999–2000 represents Fiji and Hawaii, and 2005, Tahiti.)

with the number of species arising per colonist varying from 1 to 91. If colonization commenced on the oldest current high-elevation island of Kauai (which appears to be true for most groups), 53 successful colonizations per million years would be required to give rise to the current biota. In 2005, there were 1,162,000 aircraft operations (takeoffs and landings) in the Hawaiian Islands, carrying approximately 33,300,000 passengers, 500,000 t of cargo, and 130,000 t of mail. If only one out of every 60 passengers plus one out of 200 packages (assuming the average package weighs 2 lb) each carried a stray seed, and just half of these seeds became established, this would still represent an increase in the rate of colonization to the islands of 1 billion %! Clearly the Hawaiian Islands are no longer very isolated, and, even with the utmost care in preventing the introduction of new species, the ancient processes of evolution in isolation can never be recovered.

This does not mean, however, that the native environment on oceanic islands has “lost the game,” nor that we should abandon the idea of long-term preservation of the biota. It simply tells us that we need to act quickly, and that oceanic islands can provide much-needed insights into factors underlying community resistance to change, and also its ability to recover completely under intensive restoration.

Restoration

Again because of their small size and unique biota, oceanic islands provide an opportunity to examine the reality and practicality of restoration efforts. For example, dryland forests are among the most threatened of Hawaiian ecosystems, with one of the only remaining patches of the original dryland forest in Auwahi, an area on the south slope of Haleakala on Maui. Although harboring a rich diversity of native tree species, the area is largely pasture and dominated by kikuya grass. However, excellent seed sources for most species still exist. So, over the last two decades, scientists have fenced 30 acres for restoration, killed the grass, and replanted native saplings. The results have been quite remarkable and suggest that the entire area, complete with its arthropod fauna, can be recovered. The unique microcosmal nature of oceanic islands allows restoration efforts such as these, not only simply to be conducted, but also to be analyzed and interpreted to allow extrapolation of the parameters to larger and more complex continental settings.

Recognition of the acute conservation concerns impacting islands, and the lessons that they offer, is becoming increasingly recognized. A recent Conference of the Parties (COP8) to the Convention on Biological Diversity (CBD) placed island biodiversity high on the international conservation agenda. Immediate action is clearly required, not only to document and understand the unique biota that characterizes oceanic islands, but also to use the lessons learned from these relatively simple systems potentially to address more complex global issues of conservation.

Glossary

Autocatalysis Self-acceleration of certain chemical reactions that yield catalytically active products. The reaction rate of autocatalytic processes increases exponentially.

Hypercycle Cyclic sequence of self-supporting reactions between primitive prebiotic biomolecules, nucleic acids, and proteins. Hypercyclic organization of reacting systems was postulated to explain the spontaneous emergence of replicating systems. As a result of the hypercyclic reaction principle, functional characteristics of replicating molecules (i.e., phenotypes) are connected to their hereditary characteristics or their genotypes. Consequently, both phenotypes and appertaining genotypes are evaluated and selected in feedback loops.

Natural selection Preferential reproduction and survival of certain species under given environmental conditions. Growth advantages of selected individuals reflect the efficiency of their reproduction pathways.

Quasispecies Hierarchically ordered population of mutants that results from erroneous copying of a genotypic ancestor. Whole mutant distributions behave like single species. They are subjected to natural selection. The average sequence is defined as a consensus sequence that represents the “center of gravity” of the distribution. The consensus sequence is synonymous to a wild type.

Self-organization Spontaneous formation of complex structural aggregates from biological macromolecules such as proteins, nucleic acids, or lipids. The assembly pathways are usually determined by physicochemical properties of the constituent molecules.

Historical Overview

What is Life?

Currently, life appears on Earth with an immense variety of structures and functions. Despite this diversity, some invariant features exist that are common to living systems and distinguish them from non-living matter.

All life takes shape with defined individuals. Cells are the smallest individual entities capable of performing all processes for living and reproducing. They represent the elementary structural units of life. Cells do not spontaneously originate from suitable mixtures of nonliving matter. Louis Pasteur (1822–1895) was the first to disprove the idea of abiogenesis by showing that each cell results from cell division. Rudolf Virchow (1821–1902) confirmed this, noting that fusion of cellular precursors (germ cells) is the only alternative for generating new cells. Two general types of cellular organization are known: the prokaryotic type, which lacks a nucleus, and the more highly developed eukaryotic type, which harbors a nucleus. Basically, both cell types exhibit the same structure and functional organization suggesting a common origin. Simple organisms such as bacteria consist of single cells which are either prokaryotic or eukaryotic, whereas complex organisms, such as plants and animals, are highly organized multicellular assemblies of the eukaryotic type.

The different forms of life do not originate from nothing as Charles Darwin (1809–1882) discerned in his epoch-making work. He, and independently Alfred Russel Wallace (1823–1913), postulated that, instead, a continuous process of successive adaptation to environmental conditions led to the origin and development of species. Darwin also realized that evolutionary progress results from mutagenous

reproduction and natural selection. Today, this theory can be explained with twentieth-century insights into structural and chemical characteristics of living cells.

Each single cell contains an extraordinarily efficient machinery for respiration and production of energy; for absorption and assimilation of nourishment; for synthesis, storage, utilization, and transport of new products; and for production of more or less identical copies of itself. The cellular machinery is instructed by hereditary information that is carried by large molecules which are composed of nucleic acid and known as genes. They comprise the architect's plan of all cellular components and also include structural elements regulating the formation of the different characteristics of an organism. During the process of reproduction, genes also reproduce, thereby passing all instructions on to the next generation. Proteins represent the executive that is coded by genetic information. They cooperate closely with nucleic acids in order to fulfill the diverse functional and structural tasks that maintain the cell machinery. Many proteins are enzymes that act as catalysts for the reproduction of nucleic acids and for the synthesis of essential organic compounds, such as carbohydrates, amino acids, lipids, and hormones. Other proteins care for the cellular metabolism and the production of energy. The teamwork of these two molecular species, polynucleotides and polypeptides, predominantly characterizes the chemistry of living matter as we know it.

Generally, high-energy macromolecular compounds play a major role in living organisms. In addition to nucleic acids and proteins, biomolecules such as lipids, polysaccharides, and phosphates are found. They serve for demarcation of individual cells, for their division into different subcompartments, for their structural stability, and for energy transfer

processes. However, the splendid variety of life on Earth is mainly due to the heteropolymeric nature of proteins. They consist of long chains that are built from 20 constituents, chemically defined as amino acids. Similarly, nucleic acids encoding the natural proteins are polymeric chains based on 4 different monomers. The building principle realized with both molecular species allows a variability that is far beyond the imagination—even with chain lengths of 20 monomers, more than 10^{12} different nucleic acids (with 4 different building blocks) or 10^{26} alternative proteins (with 20 different building blocks) can exist.

Structural variability is not the only feature that characterizes the molecules of life. Nucleic acids are also capable of serving as templates for their own replication, thereby guaranteeing the reproduction of living organisms. Self-reproduction is an inherent property of polynucleotides that is based on physical interactions between their complementary constituents. This phenomenon is known as base pairing and allows the synthesis of a unique complementary copy of each molecule. Replication of this copy then yields a copy of the original chain. The complete procedure very much resembles the positive-negative printing used in photography. Occasionally, the copying process is imperfect, leading to mutations in gene replication. A mutation alters the genetic information and therefore the instructions for one or more characteristics. Continuous replication and mutation can then produce genetic variability. Following expression (i.e., translation of nucleic acids into proteins), some mutations will produce altered characteristics that are favorable for the organism. This organism will reproduce preferentially over those with the unchanged gene. By far most mutations are deleterious, leading to reduced replication or even cell death. Only beneficial mutations which occur accidentally result in organisms with better adaptation to their environment. In this way, organisms evolve toward higher fitness and often toward greater complexity. In summary, complex organisms evolved through time according to Darwin's theory because of replication, mutagenous replication, natural selection, and replication of resulting mutants. During the process of Darwinian evolution, information is created continually.

Another view of "life" is presented by the discipline of thermodynamics that distinguishes between open and closed systems. Corresponding to the second law of thermodynamics, no processes can occur in closed systems that increase the net order of the system or that decrease their entropy. In this perspective, any living organism is an open system that exchanges energy and matter with its surrounding, thereby establishing and maintaining a highly ordered structural assembly at the expense of a larger decrease of order of the universe outside. Living organisms participate in ecosystems and depend on resources found in their environment. In particular, most organisms are dependent on the flow of sunlight, which is absorbed by plants and utilized by them to synthesize high-energy molecules from simpler ones. These products serve as a source of food and energy for other links of the food chain (e.g., animals). By excretion and degradation of dead organic compounds, all material will be recycled without altering the organisms' state of life, which is characterized as being far from thermodynamic equilibrium. A state of thermodynamic equilibrium would be identical to a

state of maximum entropy and thus correspond to cell death.

All organisms on Earth are closely related and the fundamental pattern of their life is essentially identical for all of them. The similarity among all living organisms probably implies that life is descended from a single instance of origin. This incident is central to many scientific and philosophical problems and the object of various different and contradictory hypotheses which will be described in the following section.

Hypotheses and Theories on the Origin of Life

The traditional position of theology and some philosophy views the origin of life as the result of a supernatural event which is permanently beyond the descriptive powers of chemistry and physics. In its most general form, this view is not necessarily contradictory to contemporary scientific knowledge about prebiotic evolution, although the biblical descriptions of creation given in the first two chapters of Genesis, taken literally and not metaphorically, are inconsistent with modern knowledge.

Until the mid-seventeenth century, the prevailing opinion was that God created man together with higher animals and plants, but that simple forms of life such as worms and insects arise steadily from mud, waste, and putrefied matter during short periods of time. The physiologist William Harvey (1578–1657), who studied reproduction and development of deer, was the first to challenge this view by postulating that every animal comes from an egg ("*omnia viva ex ovo*") a long time before Karl-Ernst von Baer (1792–1876) discovered the existence of human egg cells by microscopy. An Italian scientist, Francesco Redi (1626–1698), found Harvey's idea to be true, at least for insects; he found that maggots in meat arise from fly eggs. Later, Lazzaro Spallanzani (1729–1799) discovered that spermatozoa were necessary for the reproduction of mammals. Before Pasteur, Spallanzani also showed that living matter ("*infusories*") does not originate from boiled fluids kept in closed containers. Although Redi's and Spallanzani's findings definitely proved that insects and larger animals develop from eggs, it remained obvious to a large majority that at least microorganisms, because of their ubiquity, are generated continually from inorganic material. The debate of whether life is spontaneously generated from non-living matter or not culminated in the famous controversy between Louis Pasteur and Félix-Archimède Pouchet (1800–1872) which Pasteur won triumphantly. He showed that even microorganisms in fluids come from germs floating in the air, and he also demonstrated that nutrient solutions could be guarded against these creatures by suitable sterilization such as filtration or boiling. However, contemporary scientists were not satisfied by Pasteur's experiments because a delicate question remained: If living organisms do not arise from non-living matter, how had life come about in the first place?

In the late nineteenth century, another hypothesis was initiated by the Swedish chemist Svante Arrhenius (1859–1927). He strongly believed that the whole universe is replenished with living germs, a phenomenon that he called "panspermia." He suggested that microorganisms and spores

of cosmic origin spread from solar system to solar system, and thus they arrived on Earth. Although Arrhenius' view avoids rather than solves the problem of the origin of life, and despite the extreme unlikelihood of microorganisms surviving the interstellar effects of cold, vacuum, and radiation, a few twentieth-century members of the scientific community returned to the idea of panspermia. Among these scientists are astronomer Fred Hoyle (1915–) and molecular biologist Francis Crick (1916–), who are convinced that the time span between the origin of Earth and the appearance of first cellular organisms on this planet was too short for life to have occurred spontaneously.

Darwin's theory of "natural selection as motive power for evolution" resulted in a new view on the phenomenon of life that is still valid. Although Darwin did not commit himself on the origin of life, contemporary scientists such as Thomas Huxley (1825–1895) extended his idea, asserting that life could be generated from inorganic chemicals. Pursuing this opinion, Alexander Oparin (1894–1980) was the most influential advocate of the successive origin of cellular organisms from non-living matter. He suspected this transition was proceeded by a series of regular and progressive chemical reactions under the physical and chemical conditions on early Earth. Together with John Scott Haldane (1860–1936), Oparin recognized that the abiological production of organic molecules in the current oxidizing atmosphere of Earth is highly unlikely. Instead, both suggested that the beginning of life occurred in primordial hot waters under more reducing (i.e., hydrogen-rich) conditions. Furthermore, Oparin postulated the existence of pre-cellular coacervates—globular units with membrane-like surface structures—that may have high concentrations of certain chemical compounds. Coacervates indeed form spontaneously from colloidal aqueous solutions of two or more macro-molecular compounds.

However, many fundamental problems on the transition from non-living to living matter remained unsolved. The central question concerned the role of the second law of thermodynamics, which defines the equilibrium in an isolated system as a state of maximum entropy that appears to contradict the origin and existence of highly ordered living organisms. Erwin Schrödinger (1887–1961) gave a decisive answer to this question, stating that "living matter evades the decay to equilibrium" or death by steadily compensating for the production of entropy. In any organism, this is achieved by feeding it free energy or energy-rich matter which is used by the cellular machinery to drive essential chemical reactions. Schrödinger and others also realized that living organisms can thermodynamically be described as open systems, but they could not explain the general physical conditions for self-ordering processes. These were perceived by Ilja Prigogine (1917–) and Paul Glansdorff (1904–1999), who worked on a thermodynamic theory of irreversible processes. According to Prigogine, selection and evolution cannot occur in equilibrated or nearly equilibrated reaction systems, even if the right types of substances are present. Instead, certain combinations of autocatalytic reactions with transport processes may lead to peculiar spatial distributions of reaction partners, called "dissipative structures." These ordered structures are of importance for the formation of functional order in the evolution of life,

especially for early morphogenesis. However, the first steps of self-organization probably involved little organization in physical space but extensive functional ordering of a tremendously complex variety of chemical compounds. Manfred Eigen (1927–) explained the process of ordering among molecules by augmenting the Prigogine–Glansdorff principle with phenomenological considerations on the behavior of self-replicating molecules: A certain quantity approaches a maximal value in any open system that is replicating autocatalytically with sufficient fidelity, and thereby continually consuming energy and matter. This quantity is called "information" and is closely related to the "negative entropy" postulated by Schrödinger. In addition to setting the stage for a molecular interpretation of biological information, Eigen developed the mathematical models for describing "selection." According to Eigen's theory, selection is the fundamental natural principle that brings order into any random arrangement of autocatalytically replicating species. With selection, information is generated successively, leading to a steady optimization of species, which can either be organisms or molecules.

The mathematical models developed by Eigen support a detailed hypothesis of the origin of life which comprises multiple, successive steps for the transition from inorganic to living matter. However, it should be mentioned that some scientists have theories on the emergence of life that differ from Eigen's theory. Among these is Stuart Kauffman (1939–), who believes that natural selection is important but not the sole ordering principle of the biological world. Instead, he considers spontaneous self-organization to represent the predominant source of natural order. Kauffman demonstrated that sets of inter-related autocatalytic reactions can undergo a transition to a newly ordered (i.e., self-organized) state as soon as their connectivity reaches a certain threshold value. Furthermore, Kauffman emphasizes that the phenomenon of autocatalysis, which plays the central role in his theory, is not limited to nucleic acids. Therefore, he concludes that even genes were not necessary for the origin of life. In contrast to Kauffman, Eigen distinguishes "random" autocatalytic or self-replicating activity which is observed for a variety of molecular species from the "inherently" self-replicating nucleic acids. Inherent capability for self-replication, in turn, represents the molecular basis for natural selection according to Eigen's theory.

Well-defined experiments were invented in order to simulate the principles that were postulated for molecular evolution. With certain experimental set-ups, replication and selection can be performed in a test tube. Similarly, the chemical conditions on primordial Earth can be mimicked in the laboratory. Several scientists attempted to verify experimentally the twentieth-century ideas on biogenesis. Their experiments are discussed in the following section.

Experiments

Production of Building Blocks and Polymers

The ideas of Oparin and Haldane inspired the first simulations of prebiotic conditions on early Earth. Under the auspices of Harold Clayton Urey (1893–1981), graduate student

Stanley Miller (1930–) attempted to simulate the primordial chemical processes in a famous experiment. He continually exposed a mixture of methane, ammonia, hydrogen, and water vapor above an “ocean” of boiling water to sparks of a corona discharge in a closed apparatus (**Figure 1**). The gaseous reaction products were condensed in a cooler, dissolved in boiling water, and recirculated to the gaseous atmosphere. After several days of exposure to sparking, the aqueous solution changed color. Subsequent analysis indicated that several amino and hydroxy acids had been produced by this simple procedure. Because on early Earth probably much more energy was available in ultraviolet light than in lightning discharges, astrophysicist Carl Sagan (1934–1996) and colleagues altered Miller’s experimental conditions. They synthesized amino acids by applying long-wavelength ultraviolet irradiation to a gaseous mixture of methane, ammonia, water, and hydrogen sulfide. Similar to Miller’s experiment, these attempts also revealed that amino acids, particularly the biologically relevant ones, form readily under simulated primitive conditions. Also, it became obvious that reducing conditions were necessary for prebiological formation of amino acids since no yield was observed with oxidizing atmosphere. Further modification of these types of experiments showed that alkaline conditions led to the spontaneous synthesis of a variety of sugar molecules, including the five-carbon sugars fundamental for the formation of nucleic acids and six-carbon sugars such as fructose and glucose, which represent common metabolites and structural building blocks in contemporary organisms. As was shown by Juan Oró (1923–) and several other investigators, nucleotide bases and porphyrins can also be synthesized from simple mixtures of ammonia, water, and hydrogen cyanide. Therefore, it seems probable that most—if not all—essential

building blocks of proteins, carbohydrates, and nucleic acids can be produced under quite general primitive reducing conditions.

The formation of polymers, long-chain molecules made of repeating units of the building blocks, would have to be the next major step during chemical evolution. However, polymerization of monomers was not achieved in the simple experiments described previously. These reactions involve the loss of one water molecule during the formation of each two-unit product and therefore are facilitated under dehydrating conditions. By dry heating of amino acid mixtures, Sidney Fox (1912–) accomplished the condensation reaction in the laboratory to yield polyamino acids. He observed that these molecules were not random polymers and they also exhibited some distinct enzyme-like catalytic activities; therefore, he called them proteinoids. In addition to this work, various experimental approaches concerned the catalysis of polymerization reactions by mineral surfaces, which may also protect growing chains from degradation by water molecules, as well as combinations of heating under dry and wet conditions mimicking the environment of submarine hydro thermal vents.

Some scientists cast considerable doubt on any contribution of prebiotic syntheses of organic compounds to the origin of life. Predominant among these is Günther Wächtershäuser (1938–), who imagines an origin without reducing atmosphere and without the primordial soup. According to Wächtershäuser, prebiotic chemistry began on the surface of minerals in the lithosphere. If these minerals were positively charged, they would form ionic bonds with negatively charged chemical groups of phosphate, carbonyl, or sulfide. As a result, a layer of negatively charged molecules would form, coating the minerals in two dimensions. Once a diversity of molecules accumulated, inorganic reactions involving the minerals could supply reducing power for the synthesis of more complex organic molecules from various possible interactions within the two-dimensional layer.

The most important implication of Wächtershäuser’s theory is that the first forms of life could have been autotrophic instead of heterotrophic. Autotroph organisms get their carbon from carbon dioxide, whereas heterotrophs get it from organic molecules such as glucose. The fact that the oldest microfossils appear to be photoautotroph blue-green bacteria supports the autotroph hypothesis. Nevertheless, these ideas have not been adequately tested.

Evolution Experiments

The onset of self-replication—following the formation of polymeric nucleic acids—represents a major difficulty for the explanation of the origin of life. Experimental attempts by Leslie Orgel (1927–) and coworkers revealed that, under prebiotic conditions, it is possible to add monomeric units, called nucleotides, to complement a small template nucleic acid molecule and to combine the adhering nucleotides to the correct negative copy of the positive original. This is merely the first step of a self-replicating process that must be continued by a separation of both strands, positive and negative, and by repeated addition and concatenation of monomers. Without proteins supporting the polymerization of the building blocks, identical copies of the original nucleic acid

Figure 1 Simulation of prebiotic chemistry by Miller and Urey. Methane, ammonia, and hydrogen are led into the apparatus via stopcock 1 (top), driven into the reaction vessel by water vapor, and exposed to sparks of a corona discharge. The organic gaseous reaction products are condensed and dissolved in boiling water. Samples for analysis can be taken through stopcock 2 (bottom).

molecule, the positive strand, could not be synthesized. However, because the simultaneous emergence of self-replication of nucleic acids and specific catalysis of their duplication by proteins seems very unlikely, Orgel, together with Francis Crick and Carl Woese (1928–), supposed that the first and primitive self-replicating systems involved nucleic acids only. The discovery of catalytically active nucleic acids, or ribozymes, by Thomas Cech (1947–) and Sidney Altman (1939–) decisively supports this hypothesis. Much contemporary work therefore focuses on searching for ribozymes catalyzing the replication of nucleic acids.

Experimental studies on selection among replicating polynucleotides were first performed by Solomon Spiegelman (1914–). He purified nucleic acid and the replicating enzyme of bacteriophage Q β and implemented their replication reaction in a test tube which contained all essential reagents. Then he replicated the viral nucleic acid in serial transfer experiments by applying constraints that select exclusively for higher replication rates (Figure 2). Beginning with infectious nucleic acid molecules, sequences were obtained after several rounds that replicated several times faster and had much lower molecular weights than the original molecules but were unable to infect bacteria. On the basis of more detailed knowledge of this replication reaction, Christof Biebricher (1941–) and coworkers, together with Manfred Eigen, repeated Spiegelman's experiments. They applied conditions which were chosen to be optimal with respect to rate of evolution, and they analyzed the stepwise progress of the optimization procedure. Their attempts at facilitating artificial evolution established an "irrational" technique for the design of new drugs known as directed molecular evolution. Eigen and coworkers also performed evolution experiments with various different replicators, either molecules or viruses, and they observed functional organization between replicators and their catalysts as well as some of the molecular mechanisms of evolutionary optimization.

Theoretical Concepts

Quantitative Treatment of Darwinian Evolution

The process of complementary reproduction of self-replicating molecular assemblies can be described in detail by applying the mathematical formalism of chemical kinetics. For any population of molecules within a certain environment, consideration from the viewpoint of kinetics accounts for three necessary conditions: metabolism, self-reproduction, and mutability.

Metabolism describes the rates of formation and decomposition of each molecular species taking part in the competition. The term metabolism expresses the continuous influx of energy-rich matter, which maintains the chemical reaction, and the corresponding efflux of decomposition products. In the case of nucleic acids, the influx is due to their energy-rich building blocks, nucleoside triphosphates. The respective mono-phosphates result from decomposition by hydrolysis, or by enzymatic cleavage of polymeric strands, and represent the efflux. Metabolism by consuming and processing resources thus effects a dependence of the replicating individuals on their environment.

Self-reproduction is due to the self-accelerating or autocatalytic replication of nucleic acids. The amount of descendant molecules in a defined environment depends on the rate of the replication reaction, which is dependent on the sequence of each replicating molecule. Fluctuations of the reaction rate may also be due to variations of substrate concentrations resulting from influx and outflux within an open system.

Mutability takes into account the quality of replication. The copying fidelity is physically limited because irregularities occasionally occur during the recognition and interaction of complementary strands. Therefore, errors are introduced into the replicating molecules which lead to an increase in the variety of the offspring.

The combined considerations can be expressed in differential equations, which are used to calculate the parallel

Figure 2 Scheme of the serial transfer principle performed by Spiegelman. A series of test tubes contain Q β replicase, RNA building blocks (nucleoside triphosphates of A, G, C, and U), and necessary growth factors. The mixture is supplied with RNA template, and the reaction is started by increasing the temperature to 30 °C. When a certain product concentration is reached, a small fraction of the mixture is transferred to the next tube and incubated in the same way. The procedure is repeated many times, continually reducing the incubation period. Eventually, a single optimal RNA product is selected.

growth of molecular individuals within an expanding population. Similar to the constancy of generalized forces or fluxes in the thermodynamics of irreversible processes, the reaction equations describing autocatalytic growth of nucleic acids can be simplified on the basis of certain constant boundary conditions. In the case of constant fluxes or constant organization, the equations can be solved exactly and result in explicit expressions. The physical interpretation of the results reveals that selection in the Darwinian sense is an inherent property of autocatalytically replicating populations of molecules. Selection can be characterized by an extremal principle which mathematically describes the preferential treatment of those replicators which maximize their fitness with respect to the environmental constraints. These optimal mutants, or more precisely mutant distributions, succeed at the total expense of the others. Analogous to the concept of species that Darwin believed to be the target of “survival of the fittest” within the process of natural evolution, the selected mutant distribution with the most efficient replication pathways behaves like an individual species; therefore, it was called “quasispecies” by Eigen. The substitution of less advantageous by more advantageous mutant distributions results in reaction rate changes in opposite directions—similar to those calculated by Prigogine and Glansdorff for simple autocatalytic processes far from thermodynamic equilibrium. Hence, the instability associated with the selection process is in accordance with the expectations drawn from the Prigogine–Glansdorff principle: It results in the breakdown of the formerly (meta-) stable quasispecies and its substitution by a new quasispecies.

The quasispecies behaves physically and mathematically like a single species, or more precisely like the selected wild type of a species, but does not define a single species. It includes all mutants of the dominant form and represents a widely dispersed, not necessarily symmetrical, distribution of similar and related, but by no means identical, sequences. A quasispecies is usually characterized by a defined average sequence, called a consensus sequence, and can be dominated by one or more so-called master sequences. Evolutionary progress of the quasispecies results in new mutants that appear on the periphery of the distribution. Selection, or the emergence of mutants which replicate more efficiently than their ancestors, is a manifestation that new genetic information has been generated.

The Informational Aspect

What Is Information and How does it Originate?

In the most common sense, information is associated with the content and meaning of a “news” message. From the viewpoint of a recipient, the news can be understood only if the recipient and the transmitter agree on the meaning of the symbols used to code the message. In other words, new information is gained by a recipient when he or she can interpret the received symbols or the elementary units of information. Genetic information is stored in the linear copolymers of RNA and DNA. The number of monomers, representing the symbols, and their sequence within the polymeric chains designate whether or not a molecule encodes a message, and the arrangement of symbols determines the molecule’s

information content. The meaning of the symbols originates with the unique ability of RNA and DNA to recognize and “read” themselves. Their reading is based on particular chemical interactions mediated by specific hydrogen bonding that links the four monomers, A, T (U in the case of RNA), G, and C, into the complementary pairs AT (AU) and GC. The encoded messages transmitted by RNA and DNA include instructions that initiate and control all biochemical reaction cascades taking place within each organism.

During the process of selection, mainly the individual abilities to replicate are assessed with respect to the requirements of a given environment. The most efficient replication pathways, in turn, are “instructed” by genetic information. Therefore, new information is generated by erroneous replication and selection.

Maximal Information Content of the “Species”

Evolutionary flexibility represents the pivot of the selection process. It is guaranteed by replication error rates that produce a sufficiently large variety of mutants. However, as the mutation rates increase, the accumulation of errors outweighs the selective narrowing down. As a consequence, the genetic information “melts” away into random combinations of symbols that correspond to nonsense messages without any ability to generate and maintain necessary reaction pathways. This is a catastrophe for every living organism because it leads to the evolutionary decay of information. Therefore, natural evolution processes are bounded by an error threshold. Far below this boundary, selection can be reduced to all-or-none decisions. Evolutionary progress is achieved at reasonable velocities only when the error rate is near the threshold value. Indeed, it has been established experimentally by Esteban Domingo (1942–), Charles Weissmann (1931–), Lawrence Loeb (1936–), and several other research groups that viruses (which, due to their short replication periods, are ideally suited for evolutionary studies) behave like quasispecies and replicate close to their error thresholds. In accordance with theory, the reciprocals of the error rates that have been experimentally determined for many viruses define the limiting information capacity of their genomes. Loeb was also the first to prove the hypothesis that an additional increase in the mutation rate would abolish viral replication. By applying deoxynucleoside analogs to HIV replicating *in vitro*, he observed a complete loss of viral replicative potential and thus a lethal mutagenesis.

Generally, the theoretical and experimental results on replication error thresholds are not just true for viruses. They also remain valid for all replicating individuals that can be described by the formalism developed by Eigen (Table 1).

The complexity that life has developed by successive evolutionary optimization does not just result from vertically transmitted point mutations. (“Vertically” expresses the hereditary transmission of errors to the direct offspring.) Additional principles for the modification and expansion of genomes exist that enable the horizontal transfer of genetic information, i.e., the transfer between individuals or species. These additional principles are homologous genetic recombination, the basic mechanism of sexual heredity, and the transposition and integration of genes via mobile information-carrying elements, such as plasmids and viruses.

Table 1 Stepwise Expansion of information capacity during the evolution of life

Replication process	Subject/organism	Error rate	Maximal genome length	Example
Enzyme-free replication (base pairing)	AU polymer	10^{-1}	10	80 (tRNA ancestors)
	GC polymer	10^{-2}	100	
Enzyme-catalyzed RNA replication	RNA viruses	10^{-4}	10^4	4500 (bacteriophage Q β)
Enzyme-catalyzed DNA replication	Prokaryotes	10^{-7}	10^7	4×10^6 (<i>Escherichia coli</i>)
Recombinative, enzyme-catalyzed DNA replication	Eukaryotes	$\leq 10^{-10}$	10^{10}	3×10^9 (man)

Hypotheses on the Hypercycle as an Ordering Principle

Erroneous autocatalytic copying is the reason for selection and for the emergence of cooperation between nucleic acids and proteins. In the beginning of the prebiotic era, nucleic acids probably were the first self-replicating entities. The fidelity of their replication was mainly dependent on the stability of the complementary base pairs AU and GC that formed during the copying procedure. Based on their different hydrogen-bonding energies, very high error rates resulted that reached 1:10 for AU-rich polymers and 1:100 for GC-rich polymers. According to theory, these error frequencies led to a maximal information content comprising 10–100 symbols for nucleic acid replicators. However, even small enzyme molecules are coded by more than several hundred nucleotides, i.e., far beyond the critical value that is defined by enzyme-free replication. Thus, an information crisis resulted from the error threshold relation: Any increase in the coding capacity required a decrease in the replication error rate, and this in turn could be achieved only by application of error-correcting mechanisms. Contemporary replication machineries achieve “proof-reading” with protein enzymes replicating the genetic information which is stored in double-stranded DNA. In contrast to RNA, a newly synthesized daughter strand of DNA remains associated to its parental strand and thereby enables the comparison of both sequences. False incorporations can be identified by enzymes that test the shape of the double strand for true base pairing and that correct unpaired or mispaired regions by substitution. However, how did the first replication machinery with error-correcting facilities evolve if the coding capacity needed for it could not faithfully be replicated without the very machinery? RNA might represent a major connecting link as was demonstrated recently by David Bartel (1963–) and colleagues. They generated RNA that synthesizes RNA using the same reaction as that employed by protein enzymes that catalyze RNA polymerization. In the presence of appropriate template RNA and nucleoside triphosphates, the ribozyme extends an RNA primer by successive addition of up to six mononucleotides, thereby showing significant template fidelity.

Eventually, the limiting chain length of approximately 100 nucleotides was overcome by the capability for translation of nucleic acid into protein. The appearance of RNA molecules which acted as adaptors or interpreters between nucleic acid and protein enabled the development of feedback loops and therefore the basis for cooperation. Together with these adaptor molecules, known as transfer-RNA (tRNA), the genetic code originated. tRNAs probably arose early and played an essential role in ancient replicating systems. Even today, tRNA and tRNA-like structures are involved in a variety of replicative

processes, including replication of RNA viruses of bacteria, plants, and possibly mammals. Alan Weiner (1951–) therefore proposed that tRNA-like motifs emerged as 3′ terminal structures that tagged RNA genomes for replication before the advent of protein synthesis. These tags could have served two main roles—providing an initiation site for replication and functioning as a simple telomere, i.e., ensuring that critical terminal regions were not lost during replication.

Figure 3 (A) Schematic representation of a catalytic cycle which represents a higher level of organization in a hierarchy of catalytic schemes. The constituents of the cycle ($E_1 - E_n$) are catalysts which are formed from energy-rich substrates (S). Each intermediate E_i acts as a catalyst for the formation E_{i+1} . The catalytic cycle as a whole is equivalent to an autocatalyst. Replication of single-stranded RNA that involves mutual instruction (self-instruction) by complementary interaction represents an example of biological importance. (B) Schematic representation of a catalytic hypercycle that consists of self-instructive units with two-fold catalytic function. Each of the intermediates I_i which represent autocatalysts or catalytic cycles of the type shown in Figure 3A is able to instruct its own replication and to provide catalytic support for the production of the subsequent intermediate. For example, a simple hypercyclic process is found in nature with the infection cycle of bacteriophage Q β .

The first proteins that arose probably required more genetic information than a primitive molecular replicator was able to provide. Because more information needed to be stabilized, cooperation of differentiated nucleic acid molecules emerged that was mediated and regulated by proteins, their translation products. The enforced cooperation of otherwise competing genes allowed their mutual survival and regulated their growth. It also enabled a more refined competition–selection behavior than that among the individuals of a quasispecies. Instead of single RNA mutants, cooperative ensembles of nucleic acid and protein were evaluated according to their self-replication qualities and according to their stabilities. First, those sequences were selected as fittest that were best able to get themselves replicated as quickly and as accurately as possible by the enzyme responsible for their replication. Second, with the continual introduction of new

nucleic acid mutants, new catalytic couplings were constantly being tested.

The cooperation results in a double-feedback loop in which both the enzyme encoded by the nucleic acid template and the sequence information contribute to the replication of the template, a process called second-order autocatalysis. Phenomena of this particular kind were named “hypercycles” by Eigen and coworkers.

Hypercycles exhibit three major characteristics. First, they consist of coexisting and cooperating quasispecies, each of which is replicating autocatalytically and thereby maintaining competitive growth, selection, and its specific genetic information. Second, some of the coexisting quasispecies replicate and evolve independently. Finally, others form cooperative units within the hypercyclic organization and evolve together with mutual advantage. In an extreme case, some species as

Figure 4 Stages of emerging life.

well as quasispecies may exist only by participating in hypercyclic organization. As a whole, the cooperating units can compete with other hypercyclically replicating systems.

The overcoming of the information crisis of self-replicating nucleic acids probably proceeded via hypercyclic coupling as shown in **Figure 3**, and it supported the emergence of “translation” from nucleic acid into protein. It is assumed that hypercycles represent one major step in the organization of complex reaction networks which arose as naturally and continuously as did quasispecies. Experimentally, hypercyclic organization and its efficiency were demonstrated by Eigen and coworkers to mainly determine the infection and replication cycle of a simple bacteriophage such as Q β .

From Hypercycles to Cells

All life on Earth is cellular and reproduces only when this complex replicative unit, the cell, divides. Among the obvious advantages of cellular organization are protection of the cell's content from fluctuations of resources in the external environment and the maintenance of internal concentration gradients necessary to drive chemical reactions. Nevertheless, these facts do not explain the necessity for cellular organization: Instead, the origin of spatially limited reaction systems from a homogeneous prebiotic soup appears to be a result of problems in information processing.

Although hypercycles are the essential organizational form for the transition from self-replicating molecules to reproductive, multi-molecular machineries, they do not represent the ultimate optimum of organization. Hypercycles and quasispecies share a substantial evolutionary disadvantage: Both quasispecies competition and hypercyclic cooperation evaluate only the phenotypic properties of replicating nucleic acids, i.e., their replication rates and their stabilities. Hypercyclic coupling enables the discovery of molecular replicators which are beneficial to one or more others, and it supports the selection of those coexisting replicator combinations which gain mutual advantage by amplifying themselves. However, hypercycles cannot evaluate genotypic properties of nucleic acid sequences or their genetic messages. In other words, they do not selectively amplify mutant sequences that demonstrate their advantages only before translation.

Primitive translation mechanisms probably gave rise to proteins that were more helpful to self-replication than miscellaneous proteins randomly occurring in a homogeneous distribution. With time, preferences between translation products and certain sequences became pronounced, and these more distinct interactions effected advantages due to more specific catalysis. Finally, the differences among the various template–catalyst interactions became so influential that each enzyme had a particular catalytic role. At this stage, selection acted not only on the kinetic characteristics (i.e., the phenotype) of the replicating sequences but also on the information content (i.e., the genotype) of the sequences. Within the enlarged information system, the amount and quality of coding genes were strongly determined by efficiency, fidelity, and rate of the catalyzing enzymes, and these in turn were the translation products of their templates. By spatial separation of individual hypercycles, selective genotypical advantages in competition with other compartments were exploited. Favorably mutated compartments could develop more strongly than others and thus evolve more quickly. The compartmentalization was accomplished by individualization of all replicative units represented by a hypercycle. This event can be viewed as the birth of the cell, the smallest living entity known to us today. **Figure 4** summarizes the complete view that results from these theoretical descriptions.

Glossary

Coexistence Ability of species to persist together in an ecological community indefinitely in the absence of any major environmental change.

Ecological community An assemblage of species occurring together in a given space and time.

Heterogeneity Variation in environmental conditions through space (spatial) or time (temporal).

Niche Pattern of response of an individual, a population, or a species to the physical and biological gradients of its environment.

Niche differentiation Differential resource use or response that results from long-term, consistent reciprocal selection.

Reciprocal selection Evolutionary change as a result of species acting as selective agents on each other through interspecific interactions.

Resource A consumable or depletable substance, such as a nutrient, water, or light, that is required by plants for maintenance, growth, and reproduction.

Trade-off Constraint on expression of a species' trait/behavior as a result of expression of a correlated trait/behavior.

Introduction

The scientific community and the public at large are expressing great concerns about the global loss of biological diversity. Currently, biological diversity is threatened worldwide by the widespread destruction of forests and by impacts of global environmental change, such as nitrogen deposition and global warming. In addition, ease of travel, the dramatic increase in the number of people who travel, and deliberate introductions of organisms into various habitats can all lead to the modification of ecosystems and the loss of biological diversity. Invasions are now rampant and may lead to a great deal of homogenization of the Earth's biota. This situation has led the renowned biologist Gordon Orians to call this epoch the "Homogocene."

If we are to understand and predict the consequences of loss of species diversity for the functioning of the biosphere, we need to ascertain what factors control patterns of species richness both within and across ecological communities. The notion of community diversity has its roots in the writings of Henry Gleason and Frederic Clements. These American ecologists differed sharply in their interpretation of the plant community. The Clementsian conception of the community assumed it to be a cohesive active unit. The notions of reciprocal selection and niche differentiation are both imbedded in this idea, although not explicitly. In contrast, Gleason thought of the community as a chance assemblage of species with overlapping physiological requirements. This view may assume that there is no interaction between species or that these interactions are incidental. More recent discussion of why there are so many species was rekindled by G. E. Hutchinson in 1959 when he asked this question in his now very famous "Homage to Santa Rosalia" paper.

Currently, there are many hypotheses about the generation and maintenance of plant diversity (see discussions in both Tilman and Pacala (1993) and Huston (1994)). Much like the Clements–Gleason debate, discussion of the maintenance of

species diversity often focuses on the distinction between theories that assume evolution has driven species to partition resources so as to prevent competitive exclusion (equilibrium) and those that explain diversity through the action of demographic dynamics and do not assume a past evolutionary history between species (nonequilibrium). Ecologists commonly favor one mechanism for maintenance of diversity over others, but it is more likely that the strength of any cause differs under different locations and circumstances. It is now critical that we ascertain what characteristics of species and ecosystems lead to the dominance of any one diversity mechanism, so that we can develop a predictive framework for determining causes for maintenance of species diversity across all ecological communities.

To move the science of biodiversity from a descriptive to a predictive discipline, we need to ascertain what mechanisms underlie global patterns of species diversity. This requires clearly defining what we mean by diversity and recognizing its importance (see Assessment of Diversity and its Functional Significance). We must then determine what biological processes lead to the development of diversity within ecological communities. In this paper, we take a predominantly resource-based approach to understanding the causes of biological diversity. We highlight why resources play a central role in the maintenance of species diversity (see Resources and Niche Differentiation: Theoretical Considerations and Resources and Resources and Niche Differentiation: Empirical Evidence) and then discuss how this resource-focused view relates to other hypotheses that have been proposed to explain global patterns of species diversity (see Additional Mechanisms for Maintenance of Species Diversity).

Assessment of Diversity and its Functional Significance

Presently, there is no agreed quantitative way to assess diversity, except to use the taxonomic species concept. However, the

use of species as the primary unit of biological diversity is not always appropriate for the situation. We have previously argued that we should focus on different components of ecological diversity depending on the patterns and processes being studied. Indeed, there is now an increasing awareness that biological diversity should encompass the full range of organizational units in ecology, from genes to ecosystems. If we wish to incorporate this broader definition of diversity into our study and stewardship of ecological communities, we must present a clear framework for the accurate assessment of diversity. Developing such a framework involves explicitly outlining the different kinds of biological diversity that should be recognized and how the level of diversity can be quantified.

In many cases, the confusion arises from not recognizing the appropriate scale for the ecological phenomenon of interest. The need for clarification of scale was first recognized by Robert H. Whittaker in 1972, when he addressed the importance of distinguishing within-and between-patch diversity (known as α -diversity and β -diversity, respectively). The temporal scale of ecological dynamics may be as relevant to our discussion of biodiversity assessment as the spatial scale. This notion is well illustrated by the need in certain systems to distinguish between apparent diversity and total diversity, which may be quite different from one other. Many ecological communities depend on an intermittent availability of resources. For example, in deserts, when water occasionally becomes available in large quantities, the number of plant species (and perhaps microbes and the animals that depend on these plants) dramatically increases. In such systems, apparent diversity, which usually involves the enumeration of the species present at a given time, can vastly underestimate total diversity. Other kinds of diversity measurement may be appropriate, depending on the ultimate goals of the study. For example, aesthetic diversity for humans may depend on the number of flower colors present in a community rather than species diversity assessed by a professional (Figure 1).

Figure 1 Changes in floral color diversity in midwestern old-field successions. Reproduced from Bazzaz FA (1996) *Plants in Changing Environments: Linking Physiological, Population, and Community Ecology*. Cambridge, UK: Cambridge Univ. Press, with permission from CUP.

Specifying what components of ecological communities should be measured has become increasingly important since expanding our definition of biodiversity. As we begin to recognize the central role that ecosystems play in the global cycling of elements, functional diversity has been identified as an important characteristic in ecological assessment. Functional diversity measures the range of energy and matter processing that a particular community can undertake, e.g., carbon uptake and nitrogen fixation. Explicit in this concept is the idea of functional redundancy, which states that often more than one species in a community can play a role in a particular ecosystem process (see chapters in Schulze and Mooney, 1993). Functional diversity may be very important in the discussion of biological diversity because the removal of a given species may be much more critical to a particular system function than the removal of another species, even one with more biomass.

Although plant communities are only theoretical constructs (see Bazzaz, 1996), much discussion has gone into the notion of biological diversity and its impact on the functioning of ecosystems. A number of recent, high-profile experiments have addressed how many species must be present for a given ecosystem to function appropriately, e.g., the Ecotron experiment (Shahid Naeem and others), field studies on California serpentine grassland communities (David Hooper and Peter Vitousek) and on midwestern tallgrass prairie communities (David Tilman and others), and the BIO-DEPTH experiment carried out at eight grassland sites across Europe. Current data in these grassland ecosystems seem to suggest that the number of species for greatest ecosystem productivity hovers close to nine. Unfortunately, there is still considerable uncertainty about what mechanisms are driving these diversity-productivity patterns (see discussion in recent BIO-DEPTH paper: Hector *et al.*, 1999). Some ecologists currently believe that complementarity in species' resource use could make a multispecies community more effective at utilizing available resources (to produce higher net productivity), while others argue that more diverse communities are merely more likely to contain more productive species (known as the sampling effect). As we currently lack a complete mechanistic understanding of the relationship between species diversity and ecosystem function and as relevant data exist for few other ecosystem types, we cannot yet know how general these results will turn out to be. In these particular experiments, the species are all somewhat similar in their behavior and no "keystone" species exists. In communities containing a species that performs a special function (such as nitrogen fixation), the removal or addition of such a species may severely impact ecosystem function, e.g., *Myrica faya* invasion in Hawaii. We must also pay close attention to species that supply unique goods and services to humans.

Resources and Niche Differentiation: Theoretical Considerations

Maintenance of species diversity is often thought to be a result of niche differentiation. This idea was implicit in much early writing on community structure that recognized that species could not coexist with one another unless they had sufficiently different patterns of resource use. As plants are predominantly sessile organisms, it is assumed that plant species that are

components of a community have coexisted and competed for a long time. In this way, they are assumed to have shaped each other's responses to the multitude of critical physical and biological resources in their local environment through reciprocal selection, which could result in niche differentiation in the long term (Connell, 1980). This idea is similar to character displacement in animals. However, requirements for niche differentiation are stringent and may not always be met. Long-term species co-occurrence is needed and the frequency of encounter between plant species will depend on dispersal patterns (see Additional Mechanisms for Maintenance of Species Diversity: Spatial Structure). In addition, reciprocal shaping of species' responses to their environment is not easy to accomplish, unless initially traits related to fitness are somewhat independent of each other. To avoid assuming that niche differentiation has taken place in the past, Bazzaz (1996) suggested previously that it is more tractable to consider copresence rather than coexistence, especially in communities with a poorly known history. Studies on the postglacial migrations of temperate tree species during the Holocene in North America have clearly demonstrated how species have moved individually across the landscape and have not necessarily coexisted in the same community for long periods of time (see papers by Margaret Davis). Here, we consider communities where species are found together without regard to whether or not they co-occurred over evolutionary time and therefore have shaped each other's responses to the environment.

While niche differentiation has been touted as a major cause of the generation and maintenance of biodiversity, particularly in late successional stable ecosystems, it was unclear for many years how the concept applied to plant communities. The notion of resource partitioning was originally developed for animal communities, where species can potentially utilize a wide range of food resources and thus can easily partition up their resource environment. This idea was harder to apply to plant communities, as plants all have relatively similar resource requirements (Connell, 1978). As a result, much ecological research has focused on trying to determine how species partition themselves along resource axes. Progress on understanding factors controlling plant community diversity has been achieved by considering species' responses to multiple resources in the environment. David Tilman (1982) tackled this issue by using a mathematical model to show that species coexistence was feasible if there were trade-offs in species' requirements for different ratios of resources. This approach clearly demonstrated the potential for a resource-based approach to contribute to explaining plant species diversity. Often, however, species' responses to environmental factors are not independent of each other. Thus, it may be more informative to develop a multidimensional response surface that approximates the response of the species to its environment (Figure 2) (Bazzaz, 1996). Gradient techniques from vector calculus now allow us to quantify these response surfaces.

In this multidimensional view of the plant niche, maintenance of diversity depends on species separating themselves along multiple resource axes, such that they can coexist for a long time. It is assumed that there must be a minimal overlap between members of a community. In 1973, Sir Robert May

Figure 2 Differential responses of two genotypes of *Polygonum* to varying light and nutrient gradients. Reproduced from Bazzaz FA (1996) *Plants in Changing Environments: Linking Physiological, Population, and Community Ecology*. Cambridge, UK: Cambridge Univ. Press, with permission from CUP.

attempted to quantify the minimum allowable overlap of the species for their stable coexistence and concluded that, if the difference between the means of their responses is more than twice that of the spread of each individual curve, stable coexistence should be possible. If species are highly specialized (narrow response curves), they do not need to position themselves very far apart on one particular resource axis to prevent competitive exclusion, whereas species that are more generalist in their resource use (wide curves) must be further separated in niche space. This kind of analysis has to be extended to multidimensional response surfaces. We still do not know, even theoretically, what the minimum overlap to allow coexistence should be when we consider species' responses to more than one critical environmental gradient.

These minimum overlap conditions for coexistence may differ for contrasting community types. For example, it is reasonably well established that plants of early successional communities have broader responses to resource gradients than do plants of late successional communities. This pattern alters the length and intensity with which species interact with one another, and thus the degree to which species partition the environment. However, it has not been determined whether this pattern results from or leads to the lower species diversity of early successional communities relative to late successional ones. Early successional plants have a near-geometric type of distribution (each species takes approximately the same proportion of resources to produce the same amount of biomass). As succession proceeds, there is a shift toward a

Figure 3 Changes in community dominance-diversity relationships during 40 years of old-field succession. Modified from Bazzaz (1975) *Ecology* 56, 485–488, with permission from ESA.

more log-normal distribution (Figure 3) and then finally, without major disturbance, a return to a near-geometric distribution. This variation in patterns of resource use between species of different successional position creates a hump-backed relationship between diversity and successional time, as predicted by the intermediate disturbance hypothesis (Connell, 1978).

We have seen that mathematical models of community structure predict that diversity is largely a function of how species partition themselves along multiple environmental resource axes. Theoretical considerations suggest that trade-offs in plant species' responses along multiple environmental gradients could permit multi-species coexistence. But, do we see such trade-offs in nature and are they sufficient to explain long-term species coexistence? In the next section, we discuss the evidence for niche differentiation in plant communities and consider whether or not the degree of resource partitioning in these communities is adequate to explain species diversity in different plant communities. Resources may be partitioning both spatially and temporally and we present evidence for both kinds of niche differentiation among plant species.

Resources and Niche Differentiation: Empirical Evidence

Spatial Heterogeneity

Most resource partitioning arguments proposed to explain species diversity assume that the environment is heterogeneous. Coexistence is possible because species have different resource requirements and are specialized to succeed on particular patch types. Diversity is maintained through the presence of an array of patch types. As our ability to measure and quantify environmental variation has improved, we have developed clear evidence that the environment is heterogeneous with regard to resources that are critical to plants. To date, however, we have not critically assessed if the degree of heterogeneity recorded by our instruments is representative of the

resource environment perceived by the plants themselves (Bazzaz, 1996). Despite this uncertainty, there is now clear evidence that, at least on the broad scale, species do partition themselves along resource axes. Studies that relate species' distributions to multiple environmental factors using either direct or indirect gradient analysis have identified numerous soil-related axes of specialization, e.g., R. H. Whittaker's 1956 work on the vegetation of the Great Smoky Mountains. Research on experimentally produced plant communities also supports the notion that species may be differentiated along soil resource axes (see studies discussed in Bazzaz, 1996).

Although plants themselves can influence their local environment and thus produce intrinsic heterogeneity within the community, much spatial resource heterogeneity is generated by extrinsic factors, the most common of which is disturbance. In fact, disturbance is judged both by change in availability of resources and by perception of that change. Disturbance events create heterogeneity in resource availability at multiple spatial and temporal scales, and these different scales can allow species to partition the environment in more ways. Awareness of the importance of disturbance events for understanding the maintenance of plant species diversity was heightened when Peter Grubb (1977) proposed that regeneration traits of species should provide a critical axis for differentiation, the so-called regeneration niche. Much of the research on partitioning along this regeneration axis has focused on the broad-scale effects of canopy disturbance, addressing differences in conditions and plant responses between gaps and closed forest. Gap creation generates variability in the light environment and has been advanced as a major factor in increasing diversity at the stand level. Broad guilds of plant species that respond similarly to gap formation (light demanding vs shade tolerant) have been identified in numerous forest communities where vertical canopy stratification creates a wide range of light microenvironments (Whitmore, 1989). More recently, sophisticated mathematical techniques have been used to classify both physiological and demographic responses of tree seedlings to light availability more precisely (see SORTIE papers of Steve Pacala, Richard Kobe, and others). Much of this research into species' responses to total light quantity has found considerable overlap in response, and species' partitioning of the light micro-environment is not usually sufficient to explain maintenance of species diversity, particular in communities with high numbers of co-occurring species, such as lowland tropical rain forest.

An additional mechanism for the maintenance of diversity arose from the gap partitioning hypothesis, originally developed by Ricklefs (1977) and applied specifically to the tropical rain forest by Julie Denslow (1980). Here, finer-scale variation in resource availability across the gap-understory continuum was suggested as a possible mechanism for coexistence in multispecies communities. Unfortunately, this hypothesis has not yet been validated in tropical rain forests, where we lack a good understanding of the maintenance of species diversity. Experimental work by Tim Sipe and F. A. Bazzaz in temperate forests in eastern North America, in contrast, provides some support for the gap partitioning hypothesis. In experimentally created gaps at Harvard Forest in central Massachusetts, we found clear micro-environmental

Figure 4 Survival (a) and growth (b) responses of striped maple (*Acer pensylvanicum*, triangles), red maple (*Acer rubrum*, circles), and sugar maple (*Acer saccharum*, squares) seedlings to canopy gap size. Data redrawn from Sipe and Bazzaz (1994) *Ecology* 75, 2318–2332, and Sipe and Bazzaz (1995) *Ecology* 76, 1587–1602.

differences between gaps of different sizes (especially with regard to light). We compared morphological and physiological responses of three co-occurring maple (*Acer*) species to this light variation and found clear evidence that the species differed in their response to gap size. Many response variables showed significant differences between large gaps, small gaps, and understory plots, and these differences often varied between species, creating distinct species' preferences for canopy gap environment (Figure 4). We also observed substantial variation in light availability between different parts of canopy gaps, due to seasonal and diurnal trends in solar patterns. This variation, however, was rarely reflected in differences in species' responses to position within the gap.

Temporal Heterogeneity

As resources vary in both space and time, species could partition their resource environment temporally as well as spatially. Temporal heterogeneity in resource availability is often not considered in discussions of maintenance of diversity, but could prove central to our understanding of species coexistence. Differences in the timing of plant developmental events, such as germination, flowering, and fruit drop,

could play a critical role in mechanisms of species coexistence. In some communities that have existed for a long time, there is evidence for clear separation in flowering between groups, e.g., Peter Ashton's work on staggered mast-flowering in the Dipterocarpaceae in the tropical rain forests of Southeast Asia. In the tallgrass prairie of the American Midwest (communities that have a long evolutionary history and great species diversity), we have demonstrated clearly how these species separate their life history events along the entire growing season, i.e., phenological separation. One can recognize three fairly distinct groups of flowering species (Figure 5). Also, in these grasslands one can observe the separation of the phenology of the introduced species, *Poa pratensis*. Although it is now considered by many investigators to be part of the tallgrass prairie, it is an introduced species (from European grasslands) that grows well in the cool portion of the season. Thus, it is able to grow at two distinct times of the year: before and after the main growing season of its competitors, the native, warm-season grasses of the community (Figure 6). In this way, this species separates its growth activity from that of the native species and reduces competition for critical resources.

This kind of phenological separation is also evident in some early successional communities where species generally have broad niches (see earlier discussion in Resources and Niche Differentiation: Empirical Evidence: Spatial Heterogeneity). In old-field communities in the American Midwest, *Chenopodium album* delays its growth and reproduction much later than all other species in the community (Bazzaz, 1996), thereby reducing competition during the main portion of the growing season. In this case, it is not clear that competition has shaped these phenological responses, as species in this early successional community have not necessarily been present together over evolutionary time. Many arguments about coexistence assume that competition has shaped the niches of co-occurring species in the past (see earlier discussion). However, in communities of unknown history, the question remains whether a species has modified its phenology by competition with the native species or was preadapted to function in these communities. An example of such preadaptation is found in the shifted daily flowering behavior of the native *Erigeron annuus* and the introduced *Lactuca scariola*. In winter annual communities of the midwestern United States, *Lactuca* opens its flowers in the morning hours 7:00 to 10:00 a.m. and requires a large number of pollinators. After 10:00 a.m., however, *Erigeron* starts to open and *Lactuca* closes its flowers (Figure 7). As a result, the pollinators shift their foraging to *Erigeron*. Thus, while both species use the same pollinators, the daily separation in the opening of the flowers ensures that both are pollinated. At first glance, this may appear to be a convincing example of niche differentiation. However, when examined carefully, one finds that the introduced *Lactuca* developed this flowering behavior in its native habitat in Europe and not by competition for pollinators in the successional fields of the Midwest.

Temporal differences in species' traits may extend to very early stages of the life cycle. The formation of seed banks that can persist in the soil for a long time may also lead to maintenance of species diversity. A persistent seed bank may buffer species' responses to short-term variation in environmental

Figure 5 Seasonal flowering patterns of a midwestern prairie community with the major species shown as separate lines. Redrawn from Parrish and Bazzaz (1979) *Ecology* 60, 597–610, with permission from ESA.

conditions and prevent irreversible population crashes. Weedy species are known to form persistent seed banks. In good years for a particular species, many seeds are produced and enter the soil seed bank. In bad years, in contrast, few seeds are produced. The species can, therefore, partition the time axis to contribute the most to future generations in years when conditions are favorable for growth and reproduction. The development of this sort of persistent seed bank has been mathematically modeled and is often called the storage effect (see work by Peter Chesson). Coexistence is promoted if species have differing sensitivities to temporal variation in environmental conditions.

Further niche axes may potentially be created through the combination of temporal heterogeneity in multiple resources (see discussion in Resources and Niche Differentiation: Theoretical Considerations). Because plant responses to a particular resource are contingent on prevailing local environmental conditions, e.g., temperature and relative humidity, the time course of resource availability patterns could critically determine a plant's performance. If resource availability is high when other conditions are favorable (i.e., resources are congruent), then plants may be able to make good use of that resource. If, however, conditions are unfavorable and plant

Figure 7 Importance of the daily timing of flowering for two members (*Erigeron annuus* and *Lactuca scariola*) of a midwestern winter annual plant community. Redrawn from Parrish and Bazzaz (1978) *Oecologia (Berl.)* 35, 133–140, with permission from Springer.

activity is inhibited to some extent, then plants may not be able to take full advantage of the resource in ample supply. Species might have different levels of tolerance for the extent of resource congruency in a given plant community (Bazzaz, 1996). Additional research by our laboratory at Harvard Forest has demonstrated that, for seedlings in a canopy gap where environmental conditions show distinct temporal patterns, resource congruency could play an important role in permitting species coexistence (see papers by Peter Wayne and Gary Carlton).

Resource Partitioning: Is This Sufficient to Understand Species Diversity?

There is now good empirical evidence for substantial resource partitioning between species in the same community.

Underlying variation in soil resources and disturbance-mediated changes in the aboveground microenvironment provide primary axes for species' specialization. Further axes may be produced by responses to multiple environmental gradients, e.g., resource congruency, and by substantial temporal separation of developmental events, such as germination and flowering. It is not clear, however, that these differences are adequate to prevent competitive exclusion in the long term, as the theoretical considerations for community-level consequences of niche differentiation in multidimensional space have not been adequately explored (*see Resources and Niche Differentiation: Theoretical Considerations*). In transient, early successional communities, this discussion may not be relevant, but in communities with a long-term evolutionary history, we certainly need to consider whether resource partitioning plays a central role in community diversity. Communities characterized by long-term species' interactions, such as the tropical rain forest and the tallgrass prairie, typically contain a high number of species, and so it is critical that we unequivocally establish the role of niche differentiation in maintenance of species diversity. To date, experimental evidence suggests that resource partitioning is not sufficient to fully explain the high species richness of some such communities, e.g., tropical rain forest. Work by Hubbell *et al.* (1999) on Barro Colorado Island in Panama demonstrated that gaps did not explain variation in species richness. Gap formation did increase seedling establishment, but this effect was nonspecific and unpredictable.

Additional Mechanisms for Maintenance of Species Diversity

Resource partitioning is clearly not the only diversity mechanism operating in plant communities containing a large number of species. species' specialization on different portions of multidimensional resource space prevents competitive exclusion by reducing the degree of interspecific interactions. However, other processes within plant communities might also reduce the extent or slow the rate of competitive exclusion. In this section, we discuss three additional mechanisms that have been suggested as causes of maintaining plant diversity.

Frequency-Dependent Effects

Mathematical models of competition clearly demonstrate that stable coexistence is possible if intraspecific interactions are stronger than interspecific ones. Weak interspecific interactions commonly arise from reciprocal selection acting over evolutionary time to produce niche differentiation. However, other intraspecific density-dependent effects could act to effectively reduce interspecific interactions. A mechanism for such density-dependent effects in species-rich plant communities like tropical rain forest was first suggested by Joseph Connell and Daniel Janzen. They both argued that the most common and dominant species in the community would be most commonly attacked by herbivores and pathogens, resulting in community-level compensatory mortality. In this

way, no single species would be able to dominate the community and reduce overall species diversity. Host-specific herbivores or pathogens could act in a similar compensatory manner, increasing the average distance between parent plants and effective offspring recruitment. Currently, however, empirical support for frequency-dependent mortality in tropical rain forests has been variable. Broad-scale examination of size-specific population dynamics of tropical trees has demonstrated negative density-dependent effects in some cases, e.g., the work of Cam Webb and David Peart in Borneo, but not others (Hubbell and Foster, 1986).

Chance

The strongest alternative theory to the hypothesis that resource partitioning determines community diversity proposes that plant communities are dynamic entities containing a random assemblage of species not organized by reciprocal selection (*see Clements vs Gleason dichotomy earlier*). According to this view, higher diversity communities result from larger regional species pools rather than from species dividing up the resource environment more finely. Under these so-called lottery model scenarios, coexistence is possible as all individuals have an equal chance of reaching a particular location and whichever individual reaches the spot first will successfully establish there.

Finding little evidence for compensatory mortality in tropical rain forests (*see above*), Hubbell and Foster (1986) have argued that these lottery models may well represent tropical rain forest dynamics and explain their high species diversity. In these communities, beyond the basic early vs late successional dichotomy, many tropical forest species are essentially ecologically identical. Fluctuations in numbers result simply from chance events, and these fluctuations lead to a random walk in population densities with no stabilizing tendencies at all. Species coexistence is possible because the time for competitive elimination is even longer than the rate of new species formation.

Can we reconcile the niche differentiation vs chance perspectives on tropical rain forest diversity? It might be that the relative importance of deterministic and stochastic processes in community structure depends on the characteristics of the particular community. Chance could play a more important role in community diversity when communities are dynamic and have a fast rate of change, e.g., the tropical forest on Barro Colorado Island. In contrast, in older communities, where the rate of change is much slower and where there is likely to have been considerable sympatric speciation, e.g., the forests of Southeast Asia, niche differentiation could be the more dominant process maintaining species diversity. Until we develop a broad conceptual model of plant communities that incorporates both deterministic and stochastic processes, it will be difficult to test these ideas explicitly. Currently, the relative importance of niche differentiation vs chance effects in structuring plant communities is not well resolved.

Spatial Structure

Implicit in the notion of the regeneration niche is the idea that trade-offs between different components of a species' life cycle

may contribute to species diversity. For plant species, different strategies can be employed during the recruitment and establishment phases of the life cycle, and these strategies could be subject to selection pressure. The importance of life cycle tradeoffs for maintenance of species diversity was effectively demonstrated following awareness of the importance of spatial structure in population and community dynamics. Incorporation of spatial structure into our conceptual models of species diversity reduces the requirements for long-term stable coexistence of species, as dominance of a community by one species is commonly prevented by restrictions on a species' dispersal capabilities. By assuming that there is indeed a trade-off between a species' competitive and colonization ability, i.e., no "superspecies" exists, Tilman (1994) was able to demonstrate that coexistence of an unlimited number of species on a single resource was possible. Although we have much anecdotal evidence that trade-offs in species' competitive and colonization abilities do exist, e.g., during old-field succession (Bazzaz, 1996), we currently do not know if the exact nature of the trade-offs is sufficient to explain multispecies coexistence. It is clear, however, that recruitment limitation is a major factor controlling the structure and diversity of both temperate and tropical forests.

As plants only interact with close neighbors, spatial structure (position of individuals within the community) is a critical consideration for plant diversity as it determines the extent and intensity of intra- and interspecific interactions. Spatial heterogeneity generated by the plant community itself, through differential species' effects on their local environment, could reduce interspecific competition between dominant species if contrasting patch types favor different species. For example, it is now becoming clear that, in many multistory plant communities, the understory herb/shrub layer may play a role in the spatial structure and diversity of the community. In a number of forests worldwide, the understory is dominated by a specific species, such as bamboo in Japan and ferns in low-nutrient forests in the eastern United States. These dense understory layers act as filters for seedlings trying to ascend to the canopy. As the density of the understory is spatially variable and dependent on resource conditions (soil moisture, light availability), the strength of this filtering capability will also be spatially heterogeneous. In experimental work at Harvard Forest, Lisa George and F. A. Bazzaz have found that ferns substantially influence conditions at the forest floor, in terms of both microenvironmental characteristics and the activity of seed/seedling predators. Examination of seedling demography patterns revealed the strong species selectivity of the fern layer (Figure 8). Red maple seedlings dominated in fern areas, while the contribution of yellow birch and red oak to seedling bank composition increased in fern-free areas. These fern-induced seedling spatial dynamics have important implications for neighborhood competitive interactions between co-occurring tree species and ultimately for species coexistence.

Spatial structure in forest dynamics may also be produced by the distribution of tree species themselves. Canopy trees can alter light and soil characteristics in the understory and thus influence patterns of seedling regeneration. When a species influences conditions at a site to promote recruitment of conspecifics, this dynamic will set up a stand-level positive

Figure 8 Variation in seedling demography in experimental fern plots: ferns removed (light shading) and ferns present (dark shading). Redrawn from George and Bazzaz (1999) *Ecology*, 80, 833–845, 846–856, with permission from ESA.

feedback with a result that this species may dominate a stand until the next major disturbance. The outcome of positive feedbacks for diversity will depend on the characteristics of the particular community. In relatively species poor temperate forests, these positive feedback effects may promote species coexistence by creating stands dominated by different species and thus reducing interspecific interactions. Sugar maple and hemlock are able to coexist in eastern United States forests as a result of each stand type favoring regeneration of its own species. In contrast, in species-rich tropical forests, these spatially structured positive feedback effects may act to encourage development of single-species stands and thus reduce overall forest species diversity.

Conclusion

Biological diversity and its maintenance remain central to the science of ecology. As we lose more and more species as a result of human activities, the need to document, understand, and evaluate biological diversity becomes increasingly pressing. In this article, we have attempted to clarify our understanding of resource partitioning, as it may influence local or regional diversity. Precisely defining what we mean by diversity is the first step in any scientific endeavor on the subject, and the way that biodiversity is interpreted will depend on the goals of the study. Understanding the functional significance of biological diversity for ecosystem processes has become particularly relevant for assessing the full impact of species loss on the functioning of the biosphere.

Any attempts to determine the underlying causes for global diversity patterns rely on a mechanistic understanding of the processes driving species diversity in ecological communities. We have evaluated the extent to which we can understand species diversity from a resource-based approach. Theory suggests that long-term species coexistence is possible if species' responses to their environment are sufficiently separated in multidimensional resource space. Empirical evidence from a wide range of plant communities supports the notion that species separate themselves along spatial and temporal resource axes. As yet, however, we have not been able to combine this information with theoretical models to establish if the degree of separation is sufficient to favor long-term coexistence and maintenance of high species diversity. Certainly, in communities with very high species diversity such as tropical rain forest, it becomes more challenging to understand coexistence in terms of resource partitioning. Other mechanisms for maintenance of diversity such as frequency-dependent mortality, chance, and spatial structure may play more significant roles in these systems. Now that we have established likely contenders for mechanisms of species coexistence, it is important that we develop a comprehensive, integrative conceptual model that can incorporate

these distinct factors into a cohesive framework of biological diversity.

Glossary

Biodiversity Includes taxonomic diversity along with habitat and genetic diversity.

Dimension Set of measurement units that are completely similar. Commonly used dimensions are length (inches, meters, etc.), time (seconds, years, etc.), and mass (grams, pound-mass, etc.).

Diversity distribution A frequency distribution showing the number of classes (usually species) that have one, two, three, etc. individuals per class (per species).

Diversity index A single number used to characterize a diversity distribution. The most common is s , the number of classes (species) into which a collection has been sorted.

Fractal Length dimension with exponent other than L^1 (length), or L^2 (area), or L^3 (volume).

Scale Unit measure (resolution, inner scale) relative to largest multiple (range, outer scale).

Scope Ratio of largest multiple to unit measure.

Biodiversity as a Measurable Quantity

Scalable Quantities

Biodiversity, no matter how it is measured, is a quantity with units on one of several types of measurement scale. Consequently, some care is needed in defining the measure of diversity at hand to obtain accurate scaling relations with area or time.

A well-defined measure of biodiversity has five parts: (i) a name, (ii) a symbol, (iii) a procedural statement that sets forth the method and conditions for measurement, (iv) a set of numbers generated by that procedural statement, and (v) units on one of several types of measurement scales. A scaled quantity is conveniently represented as a symbol equated to a set of numbers arranged inside brackets, multiplied by the unit of measurement. An example is the number of cichlid fish species found in each of six African lakes, as reported by Ricklefs and Schluter (1993):

Procedural statement	Name	Symbol	Numbers	× Units
Ricklefs and Schluter (1993), p. 358	Species richness	$S_j =$	$\begin{bmatrix} 200 \\ 136 \\ 200 \\ 7 \\ 9 \\ 40 \end{bmatrix}$	× # lake ⁻¹

In this example the lakes are listed in order from large (Lake Victoria = 69,484 km²) to small (Lake Edward = 2150 km²).

Measurements occur on one of one types of scale: nominal (yes/no), ordinal (ranks), interval (arbitrary zero point such as longitude in degrees), and ratio (true zero such as distance from the equator in kilometers). The mathematical rules for working with a ratio scale quantity (such as number of species

per island) differ from those for working with quantities on other types of scales (such as ranking of lake area from large to small in the previous example). If our interest is in scale and its effects, then we need to work with the species-abundance distribution (on a ratio type of scale) rather than the rank-abundance distribution (on a rank type of scale).

Taxonomic Diversity Distributions

Diversity studies typically employ three basic quantities: N is the number of organisms, A is the area, and T is time or duration of measurement. A collection of N organisms from a unit area A_0 during a unit period T_0 is sorted into s groups (typically species) as shown in Figure 1. Any taxonomic level can be used in sorting, but for the sake of clarity species will be used to illustrate taxonomic diversity distributions. The number of organisms n_i is recorded for each species. A familiar characterization of this taxonomic diversity is the curve of abundance across species, ranked from high (largest n_i) to low (smallest n_i , usually one organism per species). The information in the rank-abundance curve can be re-expressed (see Figure 1) as a frequency distribution $s(n_i = n_k)$. The symbol $s(n_i = n_k)$ represents the number of species at abundances ranging from $n_k = 1$ upward to the abundance n_k of the most common species in the collection. This frequency distribution shows, in full detail, the information on species diversity in a single collection of size $\sum n_i = N$, taken from unit area A_0 in unit time T_0 . If our interest is in the effects of scaling, then we will need to work with the frequency distribution $s(n_i = n_k)$, which is on a ratio type of scale, rather than with the rank abundance curve (Figure 1), which is on an ordinal type of scale.

Following practice in the literature on diversity, we can reduce the information in the species abundance distribution $s(n_i = n_k)$ to an index with a single value. The most common index is the total number of species s , obtained by counting classes or equivalently by summing the distribution $s(n_i = n_k)$ across abundance classes n_k . We might also compute Shannon

Figure 1 Collection of organisms sorted into a rank-abundance curve. Arrows show how the taxonomic diversity distribution $S(N_i=N_k)$ is constructed from the rank-abundance curve. The cumulative diversity distribution $S(N_i \leq N_k)$ is then constructed from the diversity distribution. N is the number of organisms in the collection, and S is the number of species.

Weaver diversity or the Simpson index for the collection. Both go beyond gross measures of diversity such as species number s , but fall short of describing all the information in the species diversity distribution $s(n_i=n_k)$ for the collection N .

If we obtain a second collection, again from an area A_0 during a period T_0 , we expect a somewhat different number of organisms $n_j=2$, a new set of species $s_{j=2}$ (many the same as in the first collection), and a new diversity distribution $s_2(n_i=n_k)$. With several collections $s_j(n)$, now labeled $j=1$ through jt , we have a fuller characterization of diversity. We can construct the combined distribution $S(n_i=n_k)$ across some number of collections, jt . The total number of species S across the combined collection will exceed the number of species s_j in any one collection.

If the collections were always drawn by the same procedural statement, they can be viewed as samples from a set of all possible collections having unit area A_0 and duration T_0 . The diversity distribution for this hypothetical set is $S(n_i=n_k)$. This is the species abundance distribution for the community, provided all collection sites have an equal (or at least known)

chance of appearing in the sample. The total number of species S and total number of organisms N are computed respectively as $S = \sum s(n_i=n_k)$, $N_{\text{tot}} = \sum n_i s(n_i)$. Integral signs ($\int$) replace the summation signs for distributions based on continuous values of population size n_k (May, 1975). Following May (1975) we can compare an observed distribution $s(n_i=n_k)$ to a mathematical function, allowing us to compute species numbers at unobserved values of abundance n_k . An impressive number of methods (Bunge and Fitzpatrick, 1993) have been devised to estimate S from several collections $s_j(n_i=n_k)$, taken to be samples.

When making statistical estimates from taxonomic distributions, it often proves convenient to use the cumulative distribution $s(n_i \leq n_k)$ rather than the distribution $s(n_i=n_k)$. The cumulative distribution rises monotonically from left to right, as it records the number of species with n_k or fewer organisms per species, rather than recording the number of species at each value of n_k . Both distributions express exactly the same information. The cumulative distribution is less lumpy and therefore easier to use.

Other Diversity Distributions

Genetic variability within a species can be characterized in the same fashion as taxonomic diversity. For a collection of N individuals the usual single-locus measure is the proportional presence of each type of allele $q_i = n_i/2N$. This information can be expressed as a rank-abundance distribution of allelic proportions from common (q_i large) to rare (q_i small). For convenience, the information in this distribution is reduced to an index such as the number of classes (alleles) or expected heterozygosity ($H_e = 1 - \sum q_i^2$). The information in several collections can be expressed as a rank-abundance curve for each collection and a rank-abundance curve for the combined collection. This information can in turn be reduced to an index, such as F_{st} , which compares expected heterozygosity for the entire collection H_e to the average over k collections ($\bar{H}_e = k^{-1} \sum H_e$). This approach, applied to genetic diversity at the single-locus level, can be extended to coarser classifications, such as recognizable genotypes in a population (Mallet as cited in Gaston, 1996, p. 16). If we are interested in the effects of scale on genetic diversity, then the logic of working with ratio scale quantities will compel us to take the (highly unusual) step of re-expressing the rank-abundance curve as the genetic diversity distribution $q(n_i = n_k)$, which is on a ratio type of scale. This is the frequency of genotypic classes for which there was one individual ($n_k = 1$), two individuals ($n_k = 2$), etc. This can be converted to a cumulative frequency distribution $q(n_i \leq n_k)$ to again smooth away the inconvenient lumpiness of the distribution $q(n_i = n_k)$.

We can construct a diversity distribution to summarize habitat diversity. This requires defining a collection area A divided into N units of size A_0 , which are sorted into habitat classes. From this we can construct the usual rank-abundance curve, running from the most common habitat (n_i large) to rarest (n_i small). The same information can be plotted on a ratio scale as a habitat diversity distribution $h(n_i = n_k)$, expressing the frequency of habitats found in one unit ($n_k = 1$), in two units ($n_k = 2$), etc.

Alpha, Beta, and Gamma Diversity

In 1960, R. H. Whittaker distinguished taxonomic diversity within a habitat (alpha diversity) from diversity within larger geographic units composed of several habitats (gamma

diversity). Examples of these larger units include islands, lakes, landscapes, and coastal embayments. Whittaker defined beta diversity as the among-habitat diversity, or diversity change going from a single habitat to the larger geographic unit. Later (Box 1) Whittaker added two more spatial scales or “levels”—that of point diversity within a habitat and that of regional (epsilon) diversity for broader geographic units containing smaller units, each characterized by its own gamma diversity. Whittaker presented these as convenient labels, recognizing that point, alpha, gamma, and epsilon diversity were arbitrary points on a continuum, and that the size of these units might be defined differently in any given study. Starting with Whittaker, the most effective use of these labels has been in distinguishing diversity patterns at the scale of habitats from patterns at larger scale. The labels are also useful in discussing the very different processes responsible for changes in diversity at habitat, regional, and global scales. Alpha, beta, and gamma diversity have remained in wide use during the past 40 years; point and epsilon diversity did not come in to wide use. In practice, gamma diversity is sometimes dropped in favor of two labels—within-habitat (alpha) and among-habitat (beta) diversity.

It is of note that similar sets of arbitrary labels to distinguish pattern and process over a range of spatial scales have been developed in both marine (Haury *et al.*, 1978; Box 2) and terrestrial ecology (Delcourt and Delcourt, 1988; Box 2). Habitat features persist longer in terrestrial than marine systems, and hence the time-scales associated with any given spatial scale are greater for terrestrial than marine systems (Steele, 1991; Box 2).

Concept of Scale

Multiscale Analysis

Multiscale questions naturally arise for biodiversity: How does diversity change with collection size? How does it change with area? How does it change with duration of collection? These questions can be addressed quantitatively by examining the change in a biotic diversity distribution with change in collection size N , in collection area A , and in collection duration T . For habitat diversity similar questions of scale arise: How does the habitat diversity distribution $h(n_i = n_k)$ change when the collection area A is doubled? As with taxonomic diversity,

Box 1 Alpha, beta, and gamma diversity

In an evolutionary context, Whittaker (1977) defined inventory diversity at four spatial scales or levels: the point sample, the habitat, the landscape, and the region. Differentiation diversity is defined as the change in diversity between these four levels.

Point diversity The number of species for a small or microhabitat sample within a community regarded as homogeneous. Also called internal alpha or subsample diversity.

Pattern diversity Change going from one point to another within a habitat. Also called internal beta diversity.

Within-habitat or alpha (α) diversity The number of species in a sample representing a community regarded as homogeneous (despite its internal pattern). It measures the number of potentially interacting species.

Between-habitat or beta (β) diversity Change along an environmental gradient or among the different communities of a landscape. Developed by Whittaker (1960) as a measure of packing of competing species along a gradient, it was defined as the ratio of regional (gamma) diversity to average within-habitat (alpha) diversity. Wilson and Shmida (1984) review other measures of beta diversity.

Landscape or gamma (γ) diversity The number of species in a set of samples including more than one kind of community.

Geographic differentiation or delta (δ) diversity Change along a climatic gradient or between geographic areas.

Regional or epsilon (ϵ) diversity The number of species in a broad geographic area including differing landscapes.

we expect genetic and habitat diversity to be greater in large collections than in small collections, greater in widely separated samples than in closely placed samples, and greater in large areas than in small areas. We do not expect that a doubling in area will simply double the number of habitats or the number of alleles.

There are several ways to compare diversity at large and small scales. One of the more venerable is to rate (or plot) diversity relative to island size (Figure 2). Rating diversity against area is equivalent to rating against collection size N if organism density is the same on large and small islands. Another venerable method is to make a series of collections and then plot a measure of diversity against effort, measured as the accumulated number of collections (Figure 2). These “collector’s curves” are equivalent to plots against accumulated collection size N if organism catch per unit effort remains constant across collections. Figure 3 shows the increase in diatom species number with increase in effort (number of slides). A third method, currently popular but less venerable, is to fix the unit size, measure the separation between units (in time or space), and then plot some measure of difference in diversity between units as a function of separation or lag (Figure 2). An additional method is to construct a diversity distribution from a large area and then take the average diversity distribution for each half of the area, each quarter, etc. This method of coarse graining (Figure 2) is better known in geophysics (Rodríguez-Iturbe and Rinaldo, 1997; Barenblatt, 1996) than in biology. Coarse graining expresses the same information as lagging, an equivalence that goes unrecognized. Both lagging and coarse graining assume that, on average, organism number N does not depend on distance separating samples, and hence diversity differences are due to spatial scale (separation) rather than spatial gradients in organism number N .

Figure 2 Scaling methods change the spatial scope by one of several different methods, explained in the text. For biodiversity, the traditional applications are collector’s curves (increasing the number of samples), island area curves (islands rated from small to large), and beta (β) diversity (increase in number with the number of contiguous samples along a transect).

These various methods of multiscale comparison express the same information in principle but not in practice. Lagging and coarse graining (in space) express the same information if the spatial layout is the same. In practice, somewhat different information is obtained because coarse graining is applied to contiguous units, whereas lagging is applied to separated

Figure 3 Cumulative diversity distributions from areas of increasing size (one, two, three, and four slides). Note the linear relation (on a logarithmic scale) between species number S and slide area. However, species number S represents only part of the information in the cumulative diversity distributions from areas of increasing size. Data from Patrick R (1968) The structure of diatom communities in similar ecological conditions, *Am. Nat.* 102, 173–183.

units. Collector's curves introduce time-scales. In a seasonal environment, collections made monthly for a year are expected to grow more rapidly in species number than collections made annually for a decade. Rating relative to area introduces another factor—the dynamics of population exchange within species. A plot or rating of diversity against area will differ in scope for evolutionary isolates (continents), ecological isolates (islands), partial isolates (islands in an archipelago), and quadrat samples from a larger area (Rosenzweig, 1995).

Scope

In comparing diversity within or among studies we would like to have a measure that does not depend on choice of units. To accomplish this, the scope of a quantity is defined as the ratio of its maximum to minimum value. For the cichlid example, the scope in species number is $(200 \text{ species lake}^{-1}) / (7 \text{ species lake}^{-1}) = 29$. For non-cichlid species the scope in number per lake is different: $(111 \text{ species lake}^{-1}) / (17 \text{ species lake}^{-1}) = 6$. The scope of a quantity has units that cancel and hence are expressed as dimensionless numbers, independent of units of mass, length, or time. However, the units that form the dimensionless ratio should be kept in view to avoid drawing conclusions outside the scope of measurement.

Care is required in comparing quantities with scopes that differ procedurally. One can increase the scope of collection size by increasing area from unit area A_0 to total area A_{tot} . The scope is $\Sigma A / A_0$. This generates accumulation curves relative to area: accumulation of organisms $N(A)$, of species $S(A)$, of genotypes $Q(A)$, and of habitats $H(A)$. One can increase the scope of collection size by repetitive collection at one location, resulting in accumulation curves relative to time: $N(T)$, $S(T)$, $Q(T)$, and $H(T)$. There is no reason to expect that change in diversity relative to change in spatial scope will match change in diversity relative to change in temporal scope.

Spatial scope can be expanded in several ways. Searching out a wide range of isolated units— islands in an ocean and lakes on a landscape—will increase the scope. With this method the scope is the ratio of the largest to smallest spatial unit, $A_{\text{max}} A_{\text{min}}^{-1}$. For the lake example, the spatial scope is $(69,484 \text{ km}^2 \text{ lake}^{-1}) / (2150 \text{ km}^2 \text{ lake}^{-1}) = 32$. Accruing units will increase spatial scope if these are distributed over an area. Accrual can be by adjacency (along a transect or concentric rings around a point) or by random sampling within a larger area (in statistical jargon, within the frame of all possible units). With accrual, the scope is $A_0^{-1} \Sigma A = \text{number of units}$. Lagging can apply to contiguous units; the scope is $(L_{\text{max}} - L_{\text{min}}) / L_{\text{min}}$, where L_{max} is the distance across the block or along the transect, and L_{min} is the distance across the unit block. Fine graining increases scope via an increase in the

frequency of measurement. With fine graining, the scope is $A_{\text{tot}}/A_{\text{min}}$, where A_{min} is the smallest resolvable area within a large block A_{tot} .

Temporal scope can be varied as well. In principle, one can compare short time periods with long periods, but there are no examples of this. Temporal scope increases as units of equal duration T_0 accrue; the scope is the ratio of the time series to the minimum unit: $T_0^{-1} \Sigma T = \text{number of units}$. Temporal scope also increases by fine graining down to the smallest time units T_0 within a continuous period T . The scope is T/T_0 .

Complete and Incomplete Similarity

The classical solution to the problem of change in scale has been to define two systems (such as a model boat and full-scale prototype), define groups of similar measurement units (typically mass, length, and time), and then work out the scaling from model to prototype with reference to groups of similar units called dimensions mass $[M]$, time $[T]$, Euclidean lengths $[L]$, areas $[L^2]$, and volumes $[L^3]$. If the model and prototype are completely similar (Barenblatt, 1996) then we expect that a 10-fold increase in length of prototype relative to model will result in a 10^3 -fold increase in volume.

$$\frac{\text{Volume}_{\text{prototype}}}{\text{Volume}_{\text{model}}} = \left(\frac{\text{Length}_{\text{prototype}}}{\text{Length}_{\text{model}}} \right)^3 \quad (1)$$

We also expect a 1000-fold increase in mass if model and prototype are constructed of the same material and have the same density. The scaling relation is mass $\cong$ volume $\cong$ length³. Dimensional analysis, based on the principle of complete similarity, has been notably successful in engineering and several areas of physics, including geophysical fluid dynamics. It has been notably unsuccessful with natural rather than engineered objects, or with dynamics that “lurch” rather than ticking along in a clock-like fashion.

In ecology, the failure of complete similarity was addressed by comparative methods of “hierarchy theory,” which recognizes that large-scale spatial structure or dynamics cannot be computed directly from local scale structure or rates. Using Herbert Simon’s concept of “nearly decomposable levels,” the hierarchical method describes structure or computes dynamics at two (or more) levels and then compares the results. For example, in the biodiversity literature it is customary to distinguish local or within-habitat diversity from regional (among-habitat) diversity. One widely recognized finding (Holt as cited in Ricklefs and Schluter, 1993, p. 77) is that the relation of species number to area at the habitat level (i.e., within a habitat) does not match that at the ecosystem level (i.e., among larger areas having multiple habitats).

When completely similar scaling fails, a property (e.g., coastline length) at a large scale can often be computed from the average property at a smaller scale by a power law expressing incomplete similarity (Barenblatt, 1996). The most familiar example of incomplete similarity is that of a fractal relation between coastline length and Euclidean length L . If we take large steps along a coastline and then count these as if on a straight line, we obtain a coastline perimeter of length $P(L_{\text{large}})$. If we take small steps and then count these as if in a

line, we obtain a length $P(L_{\text{small}})$ that exceeds $P(L_{\text{large}})$. The relation of the two measures of coastline length is

$$\frac{P(L_{\text{large}})}{P(L_{\text{small}})} = \left(\frac{L_{\text{large}}}{L_{\text{small}}} \right)^\alpha \quad (2)$$

In briefer form, $P(L) = c \times L^\alpha$. In even briefer form, $P(L) \cong L^\alpha$. The exponent α is not an integer, as it would be for completely similar Euclidean objects. Mandelbrot (1977) coined the term “fractal” to describe non-Euclidean objects where α is a non-integer constant.

More generally, incomplete similarity relates some property $S(x)$ to some measure x according to a power law:

$$S(x) = cx^\alpha \quad (3)$$

This relation states that when x is rescaled (e.g., by a factor of 2), the property $S(x)$ is still proportional to x^α . In the example of African lakes, how does species number scale with area? A rough scaling is obtained by applying the principle of homogeneity of scope (Schneider, 1994), which requires that all terms in an equation have the same scope. An exponent is applied to equate the scope of diversity with that of lake area:

$$\frac{s(A_{\text{big}})}{s(A_{\text{small}})} = \left(\frac{A_{\text{big}}}{A_{\text{small}}} \right)^\alpha \quad (4a)$$

$$\frac{200}{40} = \left(\frac{69,484}{2150} \right)^\alpha \quad (4b)$$

Solving for the exponent, we obtain the scaling for incomplete similarity

$$\alpha = \log(200/40)/\log(69,484/2150) = 0.463.$$

This is a rough estimate that could be improved by using regression to include more information in the scaling. Based on the rough scaling, a doubling in lake area from, for example, 2150 km² to 4300 km² is expected to amplify cichlid species number by $2^{0.463} = 1.4$ rather than by a factor of 2.

Incomplete similarity applies to cumulative frequency distributions (Figure 3) as well as to single indices such as species numbers. The scaling based on incomplete similarity is

$$P[X \geq x] = c \cdot x^\alpha \quad (5)$$

where x is again some measure of interest, such as length, area, or time. For some property (such as species per unit area) the probability distribution relative to the measure is

$$S(x) = c \cdot x^{-(\alpha+1)} \quad (6)$$

The exponent that quantifies incomplete similarity can be estimated by selecting isolated units, as in the cichlid example. The exponent can be estimated via autocorrelation techniques, which measure correlation of a quantity with itself at increasingly large spatial separations. Scaling exponents can be estimated by fine graining (Milne, 1997) or equivalently by coarse graining (Figure 2). Estimates via fine or coarse graining are equivalent to those from lagging (Figure 2), a fact that is well recognized for time series analysis but largely overlooked in the literature on spatial structure. Fine graining (or equivalently, coarse graining) has been used to quantify the

fractal scaling exponent for a variety of landscape features (Rodríguez-Iturbe and Rinaldo, 1997). Fine graining (under the name of box counting or the dividers method) has been used to quantify the scaling exponent for habitats as diverse as bare soil, leaf perimeter, seaweed, and coral heads; it has been used to quantify coastline nesting habitat of eagles, pine nesting habitat of woodpeckers, and foraging habitat of rabbits (Milne, 1997).

The dynamics of systems that are incompletely similar at small and large scales are also examined via renormalization and coarse graining (Barenblatt, 1996). Renormalization has been used to investigate the dynamics of landscapes (Rodríguez-Iturbe and Rinaldo, 1997) and population interaction (Levin and Pacala as cited in Tilman and Kareiva, 1997, p. 271). Renormalization is an appropriate technique for examining the dynamics of biodiversity, which do not proceed by evenly paced transitions, but instead jump and lurch by episodes of invasion, local extinction, speciation, and anthropogenic extinction.

Incomplete similarity provides an alternative to hierarchical (usually two-level) analysis of structure and dynamics in ecology. Currently, the hierarchical approach is more familiar and remains the dominant approach when analyzing ecological interactions (Tilman and Kareiva, 1997) or biodiversity patterns at multiple scales (Ricklefs and Schluter, 1993; Rosenzweig, 1995).

Scaling Relations for Biodiversity

The development of scaling relations for biodiversity has been vigorous for taxonomic diversity. It has just begun for habitat diversity and does not yet exist for genetic diversity. For taxonomic diversity, the history of theoretical development can be summarized briefly as a sequence of scaling relations.

$$S \cong A^\beta$$

Species number scales incompletely with area. This is the oldest and best known scaling relation in ecology, with a rich history (Ricklefs and Schluter, 1993; Rosenzweig, 1995). The scaling coefficient was recognized to be less than 1 for most situations, but values were completely empirical and could not be generalized beyond the data used to estimate the coefficient.

$$S \cong N^{1/4}$$

Species number scales incompletely with numbers according to a 1/4 power law. This relation, due to Preston, was discussed in detail by May (1975), who provided a list of models. It is worth noting that the canonical value (1/4) depends on the assumption that the taxonomic diversity distribution has a lognormal form.

$$S \cong N^{1/4} \cong A^{1/4}$$

Species number scales with total numbers and hence with area according to a 1/4 power law. Preston's canonical theory and MacArthur and Wilson's theory for isolated communities attribute the scaling to equilibrium conditions (May, 1975), but it is now known that scaling laws such as this can arise in non-equilibrium conditions (Barenblatt, 1996). This scaling

assumes that organism number N scales in a 1:1 fashion with area.

$$N \cong A^1$$

Numbers scale completely with area. This scaling will always hold for coarse graining—we can always compute the average numbers in smaller areas from numbers in larger areas. This scaling will hold on average for accumulation if we take multiple sequences of organism counts. However, this scaling is usually untrue for any one sequence of accruals because of patchiness. Often, the rate of accrual will appear to accelerate because often the densest site will be sampled late rather than early during accrual. Complete scaling of numbers N with area A^1 is easier to assume than demonstrate for islands or other isolated units.

$$S \cong A^\beta, \text{ where } \beta_{\text{island}} > \beta_{\text{block}}$$

The scaling exponent is steeper for islands ($0.25 < \beta_{\text{island}} < 0.33$) than for isolated blocks of land on continents ($0.13 < \beta_{\text{block}} < 0.18$). Rescue effects, where small populations are maintained by frequent migration from surrounding areas on continents, readily explain the shallow scaling for continental communities (Rosenzweig, 1995). Milne (1997) describes a correction factor to account for scaling effects in comparing the area of Euclidean blocks to the area of islands with fractal shapes.

$$S \cong A^\beta, \text{ where } \beta_{\text{province}} > \beta_{\text{block}}$$

Biogeographic provinces, isolated at evolutionary time-scales (Rosenzweig, 1995), have scaling exponents that exceed blocks within a province. Estimates of β_{province} fall closer to unity (Rosenzweig, 1995) than to typical values for β_{block} .

$$S(n_i \leq n_k) \cong S(A_i \leq A_k) \cong H(A_i \leq A_k)$$

Species diversity, as a distribution, scales with habitat diversity, again as a distribution. Substantial qualitative support exists as correlations of species richness with several habitat variables (Wright *et al.* as cited in Ricklefs and Schluter, 1993, p. 73; Rosenzweig, 1995), including fractal measures of habitat complexity (Milne, 1997). An analytic review, similar to that of May (1975), is needed to integrate the taxonomic diversity literature with the literature on the structure and dynamics of landscapes (Rodríguez-Iturbe and Rinaldo, 1997).

Effects of Scale

On Estimates of Diversity

Estimates of diversity and of rate of extinction are required at both local and global scales, but measurements are restricted to small scales. The principal effect of incomplete similarity on estimates of diversity and extinction rate is that it precludes intuitive scalings or extrapolations. If species number, or any other index of taxonomic diversity, scales completely with area or with number of organisms, then scaling could be handled with intuition-based 1:1 scalings. A survey could be used to estimate diversity in a larger area by knowing only the area of interest relative to the area surveyed to make the extrapolation. Extinction rates could be estimated over large areas by

knowing only what percentage of the area had been examined directly. Complete similarity of taxonomic diversity with any other quantity has yet to appear in the literature, which is vast and growing (Gaston, 1996; Ricklefs and Schluter, 1993).

Incomplete similarity poses little problem if the scaling exponent is used to interpolate within the scope at which it was estimated. Extrapolation to larger scales poses a problem because of uncertainty in choice of exponents. Extrapolation becomes possible if the scaling exponent increases in a predictable way with increase in the degree of isolation (Rosenzweig, 1995). Choosing an incomplete scaling exponent, however, remains fraught with uncertainty.

Problems of non-intuitive (incomplete) scaling and uncertainty in choice of scaling exponent attend any effort to estimate change in taxonomic diversity. For habitat diversity, the problems are less acute because remote sensing can provide maps at high resolution over large areas. Consequently, scaling exponents can be estimated over a scope wide enough to be useful, from large areas of interest down to the small scale of plots and quadrats amenable to experiment and direct measurement of population and community dynamics. The number of variables that can be sensed remotely is limited. Hence, there is need for scaling relations that connect remotely sensed variables to population variables, such as density, biomass, production, movement, recruitment, and mortality. There is also a need to connect remotely sensed variables to community variables such as extinction rate.

On Conservation Planning

Conservation planning is carried out at far larger scales than measurements of the underlying dynamics. The problem is inescapable but not solvable by intuitive modes of thinking based on complete similarity. One cannot execute a field study, and apply it with certainty to conservation issues at larger scales, using the intuitive notion that rates (e.g., per capita mortality) are independent of spatial scale (i.e., scale as A^0). Nor can one proceed on the intuitive notion that a variable will scale completely with area on a 1:1 relation. The idea of incomplete similarity has already started to take its place in conservation planning. An example is the “single large vs several small” debate over refuge size—a debate that recognizes that doubling area does not leave rates unchanged nor does it double quantities such as the number of species. Several other examples are provided by Milne (1997). The next step will be to develop incomplete scalings that are reliable and based on biologically based theory rather than empirical coefficients. One particularly exciting topic, which may soon

yield to theoretical development, is the scaling of taxonomic diversity to habitat diversity. The basis in biological theory already exists. Species lists increase by invasion or speciation, for which adaptation to habitat via natural selection is important. Species lists shrink by local or global extinction, for which change in habitat is important. There is thus the biological basis for quantitative scaling of taxonomic diversity with habitat diversity. It is a promising topic for theoretical development, for which reliable computations are needed to address urgent questions of local and planet scale change in biodiversity.

Glossary

Community The collection of all species living together in a given area. Alternatively, some designated subset, such as the avian community or the vascular plant community.

Deterministic system A dynamical system whose detailed future behavior can be predicted, in principle, for all time, assuming perfect knowledge of the system at the present.

Dynamical system A set of rules defining how certain variables change with time. Ecological models are dynamical systems representing what are believed to be (vastly more complex) dynamical systems in nature.

Dynamical variable A quantity in a dynamical system that changes with time according to the rules of the system (contrast with parameter).

Ecological model A vastly simplified mathematical representation of an ecological system intended to capture

the full system's essence. Qualitatively, ecological models are to natural ecological systems as line drawings are to full-color photographs.

Equilibrium A condition of stasis in some dynamical variable.

Parameter A quantity in a dynamical system that is fixed as part of the rules of the system (contrast with dynamical variable).

Perturbation A temporary change in one or more dynamical variables or parameters of a dynamical system due to external factors.

Population A collection of individuals of the same species, often interacting ecologically and genetically.

Stochastic system A dynamical system whose detailed future behavior cannot be predicted, even in principle, due to random forces inherent in the system.

Falling down once makes a building unstable.

—GERALD WEINBERG (1975)

Background

The Meaning of Stability

Something is said to be stable if its condition tends to remain unchanged despite external influences. The population sizes of two different species may both be relatively constant in a steady, unchanging environment, but such constancy by itself discloses nothing of the stability of the two populations. If both populations were somehow perturbed—for example, by a spring flood eliminating half of each population—and if the first population subsequently recovered to former levels while the second declined to extinction, then the first population is said to have been stable while the second was unstable. Stability is not mere constancy—it also implies an ability to recover from perturbations.

The condition that recovers from perturbations need not be as simple as a constant population value. Populations of predators and prey, for example, may have an intrinsic tendency to cycle

repeatedly through high and low values, but the cycle may be stable. Suppose the populations of a predator and its prey were both maintained at fixed levels by artificial management, such as by hunting. If the cycle returned after management ceased, then the cycle could be said to be stable, even though neither population is constant during the cycle. The cycle would be an abstract condition to which the populations return after a perturbation. In fact, the condition that recovers from perturbations can be any recognizable property of the system. It could be the number of species in the system, the collective biomass of all species together, the length of the food chain, the average quantity of nutrients leached from the soil, the degree of susceptibility to disease, or many others.

In the natural world, the stability of an object is closely tied to our perception of the very existence of that object. Any property that is unstable will not retain its condition after a disturbance, by the definition of stability. Given that the world is filled with continual disturbance, any property that is unstable is therefore likely to soon change to something else and hence not be observed. For example, if food chains beyond a certain length tend to be unstable in diverse communities, then a very long food chain, should it ever appear by

chance combination of species in an ecosystem, will eventually collapse to a length that is stable.

As human domination of global biogeochemical systems increases—including eutrophication of habitats, changes in atmospheric gases, fragmentation of habitats, distribution of toxic organic compounds, translocation of species, and a general reduction of biodiversity—the resulting perturbations test the stability of ecosystems. Also, as global changes take effect, induced changes in the systems alter the stability of their parts. Stability in ecosystems is therefore not just an abstract concept but something deeply connected to the persistence of the services on which all living beings, humans included, depend.

The Diversity–Stability Question

In the 1950s and 1960s, investigators such as Charles Elton argued that ecosystems containing more species would be more stable—less subject to fluctuations due to the myriad forces acting on them—owing to such factors as the greater number of pathways for energy to flow through them. This is the diversity–stability hypothesis. The hypothesis was generally accepted in the 1960s, although not without controversy.

Theoretical studies on the topic in the 1970s shook this general acceptance. Working with mathematical models of ecological communities, Robert May and others showed that such communities with more species were less stable: Populations of individual species returned to normal after a disturbance less rapidly as the number of species in the community increased. Although May (1974) later pointed out that certain ecosystem properties, such as total biomass of the community, can be more stable than biomasses of the constituent species, and despite objections by McNaughton (1977) and others to rejecting an accepted hypothesis based solely on theory, the acceptance of the diversity–stability hypothesis waned. During the 1970s and 1980s, ecologists generally expected that greater biodiversity would reduce stability, or at least that there was no consistent connection between biodiversity and stability.

By the 1990s, experimental evidence had accumulated that seemed to support both views simultaneously, depending on the level of focus. As the number of species increased, population densities of individual species became more variable from year to year but ecosystem parameters such as total productivity and nutrient leaching became less variable. In other words, the system seemed less stable when viewed in detail, from the perspectives of individual species, but more stable when viewed in total, from the perspective of the ecosystem (Tilman, 1999) (*see Stability Under Changing Conditions: Biodiversity and Temporal Stability*).

At the end of the twentieth century, issues concerning the effect of biodiversity on stability, and of environmental stability on biodiversity, were still being resolved, but greater biodiversity could be seen to stabilize certain important properties of the ecosystem as a whole. Many of the past controversies and apparent conflicts resulted from the application of different aspects and definitions of stability in different contexts.

Aspects of Stability

The seemingly simple idea of whether a system returns to its former condition after a disturbance has several aspects. Which is relevant depends on the ecological question at hand:

1. Does the system return to its former state after a disturbance, given unlimited time without further disturbance? This is the basic idea of stability, and if the system does return from all small disturbances, that state is said to be asymptotically stable or, commonly in the ecological literature, simply stable.
2. How much does the system fluctuate under variable conditions? This is called variability and it is typically measured statistically, for example, by the standard deviation of a time series, by the standard deviation divided by the mean, or by the reciprocal of that quantity. (The standard deviation being the square root of the average squared deviation from the mean.)
3. How small does the disturbance have to be in order that the system return? The set of all possible disturbances that allow the system to return to its former condition is called the domain of attraction. As the domain of attraction becomes vanishingly small, the system becomes unstable. Small domains of attraction correspond to fragile systems, whereas large domains of attraction correspond to robust systems.
4. How much is the system changed by a given disturbance? The more a given condition is changed, the lower the resistance associated with that condition. For example, suppose population values in a given area do not change much when average temperature increases above its normal but may change considerably when rainfall does so. Then the system would be said to be resistant to temperature changes but not to rainfall changes.
5. How fast does a perturbation decay? Resilience is the amount of time needed for a perturbation to be reduced to a specified fraction of its initial size. There has been variation in the use of this term in the ecological literature. Before the 1980s, resilience often simply referred to factors that reduced the chance that one or more species would become extinct (e.g., the size of the domain of attraction and the populations densities in that domain).
6. How long does the system take to return after a given disturbance? This is related to both how far the system is perturbed by the disturbance (resistance) and how fast the perturbation decays (resilience). The lower the resistance and resilience, the longer it takes to return.
7. How long can the condition be expected to last? The longer on average it lasts, the greater its persistence. The idea of persistence applies to systems subject to random variations, where the chance of encountering dangerously large variations during a time interval increases as the interval grows longer. The longer the time interval, for example, the greater the chance that one or more species will be driven extinct by random events.
8. Does the condition remain intact as the parameters of the system change slightly? If it does, the system is structurally stable with respect to those parameters. For example,

if precise birth and death rates of the constituent species change slightly occasionally, does the condition remain?

9. Does the condition remain intact under evolutionary pressures? If it does, the condition is evolutionarily stable. A condition may appear stable over short time, ignoring evolution, but may change on longer timescales. Indeed, over the course of geological time, no ecosystem is invariant.
10. Does the condition depend on spatial scale? What is stable in a small area may be unstable over a larger region and vice versa.

Pimm (1984) enumerated five definitions of stability in the ecological literature at three levels of complexity and three levels of organization—potentially 45 different nuances to the meaning of stability. Hence, care is necessary in defining and applying the concept.

Basic Theory of Stability

Equilibrium

The basic concepts of stability become precise when considered in the abstract. The many complexities in natural ecological communities, including factors that cannot be completely understood, mean that any abstraction of an ecological system is necessarily a vast reduction. To start this reduction, suppose the population increases solely by births and decreases solely by deaths. That is, processes such as

immigration are not active. Suppose the rate of birth is highest and death is lowest when conditions are least crowded. As the population increases, resources become more limited—less light, reduced nutrient levels, less food, and so forth; the birth rate decreases and the death rate increases. At some point, the population will increase enough so that births just balance deaths. This occurs at the carrying capacity, at which an individual, on average during its lifetime, just replaces itself with a single offspring. Above this carrying capacity, deaths exceed births, so an individual on average does not quite replace itself. In the simplest case, births decrease and deaths increase along straight lines as the population increases (Figure 1A). The net rate of change per individual (the difference between births and deaths) is largest at the far left in Figure 1A (r) but decreases to zero when the population size reaches the carrying capacity (K) and becomes negative when the population size is greater than the carrying capacity.

The rate of change of the entire population is simply the rate of change per individual times the number of individuals in the population. This is graphed in Figure 1B, which shows the growth rate of the entire population (vertical axis) as a function of the population (horizontal axis). If the population is nonexistent (zero), then of course population growth is zero; with no individuals there are no births and can be no deaths. If the population is at carrying capacity, population growth is also zero; births balance deaths. These are two population equilibria—places where the population remains constant.

Between these two equilibria, the population grows. In this simplest case, in which the birth and death rates are straight

Figure 1 Geometric interpretation of stability. Solid and open circles represent stable and unstable equilibria, respectively. (A) Per capita birth and death rates are functions of population size; (B) growth of the entire population as a function of population size; (C) populations approaching carrying capacity with the passage of time, for the functions of A and B. The horizontal axis is time; the vertical axis is the population at the corresponding time. Cross symbols at the far left indicate the starting points. Curve 1 starts from a small population near zero. Curve 2 starts above the carrying capacity. Curve 3 starts below the carrying capacity but well above zero. (D) Growth of a population subject to the Allee effect, where 0 is a stable equilibrium.

lines, the population reaches the greatest rate of growth at half its carrying capacity. (In economic models, this is called the point of maximum yield.)

Geometric Interpretation

Single Species

To understand the stability of an equilibrium, the properties of the growth rate are first examined in the near neighborhood of the equilibrium. Consider the equilibrium at the carrying capacity (solid circle in **Figure 1B** at position K). The graph representing population change crosses the horizontal axis precisely at the carrying capacity, which means the population neither grows nor declines there. At that point the growth curve slopes downward to the right (the slope is negative). If the population for any reason falls below the carrying capacity (e.g., point b in **Figure 1C**), the growth function is above the axis, meaning that population growth is positive or that births exceed deaths. Thus, the population increases toward the carrying capacity. On the other hand, if the population is above the carrying capacity (e.g., point c in **Figure 1B**), the growth function is below the axis, meaning that population growth is negative or that deaths exceeds births. Thus, the population decreases toward the carrying capacity. In both cases, an external change moving the population away from its carrying capacity induces population growth or decline in exactly the right way to counteract the external change. The population returns to the carrying capacity. That equilibrium is stable.

Now consider the equilibrium at 0 (open circle in **Figure 1B**). As before, the graph representing population growth touches the horizontal axis precisely at 0. However, at this point the curve slopes upward toward the right (the slope is positive). Therefore, if the population ever increases, however slightly, above zero (e.g., point a in **Figure 1B**)—due, for example, to the arrival of propagules from some outside source—the growth function is above the axis, meaning that population growth is positive or that births exceed deaths. Thus, the population increases away from 0. The zero equilibrium is unstable.

Thus, internal dynamics carry these populations toward their carrying capacity (which is called an attractor) and away from 0 (called a repeller). If the population starts near zero, but not precisely at zero, it may linger a long time at low values and then begin a rapid growth phase before leveling off toward its carrying capacity (**Figure 1C**, curve 1). If the population starts above the carrying capacity, it rapidly decays back (**Figure 1C**, curve 2). If it starts below the carrying capacity but well above zero, it can increase to the carrying capacity without the long lag period (**Figure 1C**, curve 3).

Local Versus Global Stability

In the previous example, the carrying capacity is said to be a global attractor or globally stable because almost all replicate populations eventually arrive there (all but those starting at zero in this case). Because the equilibrium at 0 is unstable, the population has a level of permanence; if driven to low values, but not completely to zero, it can recover spontaneously.

This contrasts with populations operating under an Allee effect, wherein the equilibrium at 0 is an attractor. **Figure 1D** depicts the growth function in such a situation. Very low densities inhibit reproduction, for example, by reducing chances of encountering a mate. There are three equilibrium points—at 0, A , and K . Slopes both at 0 and at K are negative, meaning that these equilibria are stable, whereas the slope at A is positive, meaning that equilibrium is unstable. If such populations are driven to a low enough level (below A), they will spontaneously become extinct.

In this case, both 0 and K are local attractors (locally stable), but neither is a global attractor (neither is globally stable). If the system is pushed a small distance away, it will return to its former state. However, if pushed too far (beyond the domain of attraction of that equilibrium), the system will switch to another state. This is a bistable system. The region between 0 and A is the domain of attraction of the 0 equilibrium; the region between A and K and the entire region above K make up the domain of attraction of the carrying capacity. There is no domain of attraction for the equilibrium at A because this equilibrium is unstable (it is a repeller).

Multiple Species

The geometric example of **Figure 1** represents a single species in isolation. In this case, geometric stability arguments are direct and intuitive. The geometric arguments are similar for more than one species, but instead of curves representing growth rates, surfaces in multidimensional space are used. Each additional species requires another dimension. Unfortunately, such surfaces are difficult to visualize for more than two species.

The growth surface for a single species will in general cut through the plane of zero growth (analogous to the horizontal axis in **Figures 1B** and **1D**) along a curve. This curve is called the zero net growth isocline, and each species in general will have its own such curve. If the zero net growth isoclines for many species meet at a single point, then this is a multispecies equilibrium point. For this equilibrium to be stable, however, it is not sufficient that the growth surfaces of all species, considered separately, have negative slopes there. Interactions among the species must be accounted for, and this is best done algebraically.

Algebraic Methods

The geometric interpretation of stability, as depicted in **Figure 1B**, has a direct algebraic interpretation in terms of derivatives and eigenvalues, which correspond geometrically to slopes. Where an algebraic description of the ecological system is available (i.e., in ecological models), the algebraic method is widely used and can be followed as a recipe. The algebraic method is essential for theoretical work in ecology, but the material in this section is not essential for an intuitive understanding of the concept of stability.

Single Species

Consider an ecological system of a single species in which the symbol N represents the population size. This may be measured in individuals, biomass, or other units. The rate of

Table 1 Common ecological usage vs common mathematical usage

Term	Size of perturbation with time	
	Ecological literature	Mathematical literature
Asymptotically stable	Decreases	Decreases
Stable	Decreases	Does not increase
Unstable	Increases	Increases
Neutrally stable	Remains unchanged	(Typically not used)

change of this population is represented by dN/dt , which tells how large an increment (dN) occurs in the population during a small increment of time (dt). Assuming that this rate of change is a function of the population size, as in the previous discussion, then the system will be described by $dN/dt = f(N)$. For example, in **Figure 1**, $f(N) = rN(1 - N/K)$, which is the well-known logistic equation described in most introductory ecology texts.

Equilibria are commonly designated by symbols like $\hat{N}$ (pronounced “hat N ”). They occur at such $\hat{N}$ where $f(\hat{N}) = 0$. If the slope of the function $f(N)$ at any such equilibrium is negative (i.e., if $df/dN|_{N=\hat{N}} < 0$, as shown by the solid circles in **Figures. 1B** and **1D**), then the equilibrium is stable. If the slope is positive (as shown by the open circles in **Figures. 1B** and **1D**), then the equilibrium is unstable. If the slope is zero, then further information is needed to determine stability. In the case of zero slope, the equilibrium may be stable, unstable, or neutrally stable, depending on the exact shape of the function near the equilibrium. In the ecological literature, neutral stability means that if the system is perturbed from equilibrium a small amount, it neither returns nor moves further away but rather maintains its new value. (Note that there is a difference between the way ecologists use the word “stable” and the way mathematicians do, as summarized in **(Table 1)**.)

Multiple Species

Multiple species are represented by multidimensional dynamics, in general described by m equations of the form $dN_i/dt = f_i(N_1, N_2, N_3, \dots, N_m)$, one equation for each species. Equilibria are multidimensional points $(\hat{N}_1, \hat{N}_2, \hat{N}_3, \dots, \hat{N}_m)$ that cause all dN_i/dt to be simultaneously zero. Some of the $\hat{N}_i$ may be zero, in which case fewer than m species coexist at that equilibrium.

The slope of a system in one dimension generalizes to eigenvalues of the Jacobian matrix in multiple dimensions. (In one dimension, the slope is a special case of an eigenvalue.) To determine stability of an equilibrium, (1) construct the Jacobian matrix of the system, $J = \{\partial f_i / \partial N_j\}$, (2) substitute the equilibrium value $(\hat{N}_1, \hat{N}_2, \dots, \hat{N}_m)$ into the matrix of step 1, and (3) determine the eigenvalues of the matrix of step 2. **Neuhauser (2000)** or other mathematical texts may be consulted for full details.

The resulting eigenvalues are complex numbers, and as such may contain both real and imaginary parts. (That is, an eigenvalue has the form $a + bi$, where a is the real part, bi is the imaginary part, and $i = \sqrt{-1}$). The real part determines the rate of approach to or retreat from equilibrium after perturbation. In one dimension, the imaginary part is always zero, but

in higher dimensions it need not be. When it is not zero, the approach to or retreat from equilibrium follows a spiral path.

Only the real parts of the eigenvalues affect stability. If the real parts of all eigenvalues are negative, that equilibrium point is stable. If one or more real parts is positive, that equilibrium point is unstable. If none is positive but one or more real parts are zero, then further information is needed to determine stability. If some eigenvalues have negative real parts but others have positive, then the equilibrium is a saddle point (so called because of its shape in the two-dimensional case). Such saddle equilibria are attracting in some directions and repelling in others; hence, they are unstable.

Discrete-Time Systems

Many ecological models are more naturally defined on a discrete time axis. For example, insects may emerge together at a specific time each year or seeds may be set once per year in the fall. In such models, time is better represented not as a continuum but rather as a series of integers (1, 2, 3, ...), for example, representing a series of years. In simplest form, discrete-time models have the structure $N_i(t+1) = f_i(N_1(t), N_2(t), N_3(t), \dots, N_m(t))$, where $N_i(t)$ is the population level of species i at time t . To determine stability of an equilibrium in a discrete-time system, the three steps outlined previously are followed, but the resulting eigenvalues must be interpreted differently. Again, the eigenvalues are complex numbers. In the discrete-time case, it is the absolute values of the eigenvalues that determine stability. That is, it is the positive square root of the sum of the squares of the real and imaginary parts. (For the eigenvalue $\lambda = a + bi$, $|\lambda| = \sqrt{a^2 + b^2}$.) If the absolute value of all eigenvalues is less than 1, then the equilibrium is stable. If the absolute value of one or more eigenvalues is greater than 1, that equilibrium point is unstable. If none is greater than 1 but one or more absolute values are precisely equal to 1, then further information is needed to determine stability, as in the case of zero eigenvalues discussed previously.

Strength of Return

The magnitude of the eigenvalues (or, equivalently, the steepness of slope) determines the resilience, or the strength of return to equilibrium. If the eigenvalues are all very negative, the corresponding slopes will be very steep. Small deviations from equilibrium will result in large rates of growth or decline, and the system will return rapidly. On the other hand, if any of the eigenvalues is negative but close to zero, then the corresponding slopes will be shallow. Small deviations from equilibrium will not lead to rapid recovery. Of course, given a sufficiently long time, and given the absence from disturbance, the system will return regardless of the eigenvalue's magnitude, given that it is negative. However, over short times, or with repeated disturbances, the magnitude of the eigenvalues is an important part of stability.

Stability Under Changing Conditions

Biodiversity and Temporal Stability

If a system is subject to repeated disturbances, variations in a given property of that system over time will be related to the

Figure 2 Temporal stability. Dashed lines indicate the long-term means, and solid lines indicate fluctuating variables. (A) Relatively small fluctuations about the mean, with a relatively high measure of temporal stability (8.3); (B) larger fluctuation about the mean, indicating lower stability, with a lower measure of temporal stability (2.3).

asymptotic stability of that property. Because asymptotic stability is an abstract concept, well defined in ecological models but difficult to determine in natural systems, various measures of fluctuations are often used instead to quantify stability of natural systems.

Suppose two populations are fluctuating through time about their individual mean abundance levels due to stochastic effects in the environment and possibly due to internal dynamics as well. Suppose fluctuations in the first population are on average relatively small compared to the first population's mean abundance, whereas fluctuations in the second population are noticeably larger compared to the second population's mean abundance (Figure 2). Independent of the idea of asymptotic stability, the first system can be defined to be more stable with respect to constancy in abundance. Precisely how this fluctuational stability is related to the concept of asymptotic stability discussed in the previous section is a separate theoretical issue.

The average fluctuation can be quantified in alternative ways; for example, as the average absolute value deviation from the mean or as the standard deviation of the mean. In any case, if fluctuations are large relative to the mean, the system is likely to obtain values very far from the mean. Also, if the underlying dynamics have a domain of attraction that is responsible for maintaining the mean, then large fluctuations are more likely, on rare occasions, to combine in the wrong direction and push the system out of that domain, inducing a switch to a new mode of behavior. Thus, the relative amount of fluctuation can carry information on the long-term persistence of the system.

Measures proportional to the coefficient of variation—the standard deviation over a time series divided by the mean of that time series—have been used as a measure of fluctuation. These are actually proportional to instability because larger values in the coefficient of variation correspond to lower stability. The reciprocal of the coefficient of variation (i.e., the mean divided by the standard deviation, μ/σ) has been termed temporal stability (Tilman, 1999). It carries the same information, but larger values of temporal stability correspond to greater stability of the system. In this form (μ/σ), it is

reminiscent of signal-to-noise ratio in engineering. Clearly, temporal stability is greater if the mean is greater (μ , the numerator), if the standard deviation is smaller (σ , the denominator), or both. Therefore, any forces that tend to increase the mean or decrease the variation will increase temporal stability. Temporal stability is maximal (infinite) when the standard deviation is zero—when there is no variation at all.

Evidence from both experiment and theory suggests that the temporal stability of certain community characteristics of competitive plant communities tends to increase as the number of species they comprise increases (Tilman, 1999). Along a long-term nitrogen fertilization gradient, the number of species varied, changing from diverse prairie communities at low nitrogen levels to only a few agricultural grass species at high nitrogen levels. Individual species abundances varied from year to year due to many causes, both environmental and ecological. As the number of species increased, (i) the total biomass of the community tended to increase and (ii) the total biomass of the community became less variable. Simultaneously, the biomass of an individual species tended to become more variable relative to the mean biomass for that species embedded in the community. In other words, increased biodiversity appears to stabilize the community while destabilizing the individual species.

Given this pattern from experimental systems, a theoretical question immediately arises: Do standard ecological models predict similar phenomena? This is a rapidly developing area, but initial results appear to indicate that they do (Tilman, 1999). In a model of competition for a single resource, and in other more general models, temporal stability of total community biomass increased steadily and linearly as the number of species increased (Figure 3A). Temporal stability of individual species biomass decreased sharply as biodiversity increased from one to about five species, and then it leveled off at higher diversities (Figure 3B). In other words, simple ecological models appear to predict the effects observed along the nitrogen gradient—increased biodiversity will stabilize the community but destabilize individual species.

The importance of various possible causes of stabilization of community properties remain under discussion. When abundances of individual species are perturbed by complex and effectively random forces, some abundances may be perturbed to higher levels and others to lower levels. On statistical grounds, the variation in the total biomass will likely contain both positive and negative perturbations. Hence, the total is likely to fluctuate less, relative to its mean value. This has been called the portfolio effect (Tilman, 1999) by analogy to economics, wherein a portfolio diversified over many investment instruments will fluctuate less than one containing only a few. It depends on species responding differently to perturbations, if only for statistical reasons. Effects of competition allow species to expand in abundance when a competing species is suppressed by external forces. This expansion, in turn, buffers any change in total biomass. This is called the covariance effect because it is evident when there is strong negative covariance between pairs of species. Finally, increased biodiversity also often leads to increased total abundance, and this increases stability by making any given level of fluctuations smaller in proportion. This is called the overyielding effect.

Figure 3 Biodiversity affects temporal stability. From a resource model reported by [Tilman \(1999\)](#) showing patterns similar to those observed in nature. Large dots indicate means of 100 replicates. (A) Increasing biodiversity stabilized total biomass; (B) increasing biodiversity destabilized individual species biomass.

Regardless of the source of the stabilization, however, it appears that certain composite community properties may be stabilized by increased biodiversity. More direct experiments that will eventually be able to clarify the effects of biodiversity on stability and other ecosystem properties have been established in many countries ([Hector *et al.*, 1999](#); [Tilman, 1999](#)). Results of this coordinated set of experiments will emerge during the first decade of the twenty-first century and bear watching for information they will provide on the diversity–stability question.

Temporal Niches

Temporal stability, as defined previously, certainly applies to a system continually perturbed from equilibrium. However, equilibrium was not part of the definition—only the mean and the variation about the mean participated in the measure of temporal stability. Temporal stability therefore applies to cases in which equilibrium, stable or otherwise, may not even exist.

Changing environmental conditions, such as variation in average rainfall from year to year, can favor different species at different times. This, in effect, can partition resources among species, setting up temporal niches and permitting long-term coexistence of species that greatly outnumber the resources they consume ([Chesson, 1994](#)). Without changing conditions, biodiversity would be reduced—coexistence would be limited by the number of resources available.

For a given regime of environmental fluctuations, and for a given community, each species will have some pattern of fluctuations in response to the fluctuations in the environment and those of other species in the community. Again, the issue with respect to biodiversity is how the relative size of the fluctuations—the temporal stability—of each species depends on the number of species in the community and how community-level properties such as total productivity or nutrient leaching depend on the number of species.

Coexistence among species in the absence of a multi-species equilibrium can result from stochastic variations in the environment, as explained previously. However, it is not necessary that the variations be stochastic, nor that their source be the external environment. The variations could result from some regular, well-determined periodic changes in the environment, or they could result from population cycles set up by dynamics of the ecological community ([Armstrong and McGehee, 1980](#); [Huisman and Weissing, 1999](#)). Whether the effects are external or internal, stable coexistence at increased biodiversity can exist under fluctuating conditions.

Emerging Deterministic Stability

Stable deterministic characteristics such as those described in the section on Basic Theory of Stability can emerge from stochastic systems. Individuals may live and die, populations may fluctuate in abundance, and some species may become extinct while others appear; however, amid all this complexity, simple patterns of biodiversity can emerge.

One of the early successful theoretical explanations of biodiversity concerned island biogeography ([MacArthur and Wilson, 1967](#)). On islands, simple deterministic characteristics emerge amid complex ecological change. It is a conspicuous fact that oceanic islands have fewer species than adjacent mainlands. This effect can be attributed, to a large extent, to a stable balance between local extinction of resident species and immigration of new species.

A new individual arriving on the island may be a member of a species already resident on the island, or it may represent a novel species. If the island is devoid of life, the new individual is certain to be a member of a novel species. As the island becomes more populated with mainland species, the chance that the individual is a member of a novel species decreases. Similarly, the chance that an existing species vanishes from the island increases as the number of resident species increases.

Such considerations lead to immigration and extinction curves such as those in [Figure 4](#). Notice the qualitative similarity of the immigration and extinction curves in [Figure 4](#) to the birth and death curves, respectively, in [Figure 1](#). The immigration and extinction curves intersect at an equilibrium point, where resident species becoming extinct are balanced by new species arriving. Note that at this equilibrium, neither population values nor community composition are constant. In fact, the individual species making up the community are constantly in flux. It is simply the biodiversity that remains constant.

Is this biodiversity equilibrium stable? The net rate of increase or decrease in the number of species is simply the difference between the immigration and extinction rates, which

Figure 4 Stable island equilibrium. Island biogeographic immigration and extinction curves patterned after observed rates for real islands. Biodiversity reaches a stable equilibrium when immigration balances extinction.

is the solid curve in **Figure 4**. Unlike the curves of **Figure 1A**, this net rate represents the entire island; it is not a per capita or per species rate. Therefore, its slope at the equilibrium directly corresponds to stability—it need not first be multiplied by the number of species on the island. Because the slope is negative, by the arguments of the section on Basic Theory of Stability this equilibrium is stable.

Stability Amid Chaos

Consider a population that changes deterministically according to the rules of **Box 1**—a straight-line relative of the logistic equation of **Figure 1**. Populations oscillate chaotically between high and low values, but except for certain infinitely rare starting conditions they never return to a previous state (**Figure 5**). This system is chaotic in the sense that slight deviations are always magnified. In almost all cases, two slightly different starting populations, no matter how nearly identical, grow increasingly different with time.

However, amid such complete chaos can be stability. After sufficient time, population values fall into a pair of disjoint intervals, shaded in **Figure 5**. This pair of intervals is an attractor. The population then alternates regularly between the intervals, though its position within either interval cannot be predicted for very long from measurements of finite precision. This is a deterministic system with dynamics that appear superficially stochastic, but among all its instabilities arises another level of stability.

Other Kinds of Stability

Structural Stability

In the cases discussed previously, the ecological system did not change. Dynamical variables such as population levels were

Box 1

$$N_{t+1} = \begin{cases} 2N_t & \text{if } N_t < a \\ 2a(1 - N_t)/(1 - a) & \text{if } N_t \geq a \end{cases}$$

Piecewise linear discrete-time population growth. If $a < 1/3$, there is a stable equilibrium at $N = 2a/(1 + a)$. If $a > 1/3$, there are no stable equilibria or cycles (see **Figure 5**).

Figure 5 Stable attractor enclosing unstable population cycles. The system of **Box 1** with $a = 3/8$ is chaotic, but population fluctuations are pulled into the shaded intervals (0.3, 0.48) and (0.6, 0.75). The horizontal axis is time; the vertical axis is the population at the corresponding time.

perturbed, but ecological parameters such as birth rates remained fixed. Ecological parameters, however, constantly change: Global temperatures increase, glaciers retreat, and spruce forests give way to pine and then hardwoods. Rainfall, soil substrates, and a host of environmental conditions alter the parameters and the structure of ecological systems. Hence, not only may the dynamical variables such as population abundances be perturbed but also the very structure of the ecological system may change.

If a given property of a system persists under small changes in the system itself, then the system is said to be structurally stable with respect to that property. The equilibrium carrying capacity in the system of **Figure 1**, for example, is structurally stable. Changes in the slopes of the birth and death rates, or small changes that make the birth and death rates curves rather than straight lines, still leave a carrying capacity that all nonzero initial populations eventually reach, provided that the net per capita growth declines smoothly with increasing population. The precise size of the carrying capacity may change, but the fact that it exists and is stable does not.

Classical Predator–Prey Systems

Some ecological models are on a razor edge of structural instability. In the simplest form of the classical Lotka–Volterra predator–prey system, included in most introductory ecology texts, the prey population is limited by predation and the predator population is limited by availability of prey (first pair of equations in **Box 2**). Predator and prey populations

Box 2

$$\begin{aligned}\frac{dN}{dt} &= r_N N - aNP \\ \frac{dP}{dt} &= r_P NP - bP \\ \frac{dN}{dt} &= r_N N \left(1 - \frac{N}{K}\right) - aNP \\ \frac{dP}{dt} &= r_P NP - bP\end{aligned}$$

Lotka–Volterra predator–prey system. Top two equations, no carrying capacity for prey; bottom two equations, carrying capacity included (see **Figure 6**).

Figure 6 Structural instability in Lotka–Volterra predator–prey cycling. Solid curves represent population densities of the prey, and dashed curves represent that of the predator. Here, $r_N = 1$, $r_P = 1/2$, $a = 1$, $b = 1/2$, $K = 5$, $N(0) = 2$, and $P(0) = 1/2$. (A) The prey population is limited only by predation (top two equations in **Box 2**). The populations oscillate on neutrally stable cycles. This effect is structurally unstable. (B) The same starting conditions when the prey is also limited by its own carrying capacity in the absence of the predator (bottom two equations in **Box 2**). Initial variations damp out. This effect is structurally stable.

oscillate indefinitely about an equilibrium, with the predator population lagging behind that of the prey (**Figure 6A**). This is a common characteristic of predator–prey systems or, more generally, of producer–consumer systems. However, this particular system has a peculiar property for an ecological system: It possesses a “memory” of past events. If something perturbs either population, or both populations, to a new level, that new level will be revisited on each subsequent cycle. This system has no asymptotically stable behavior; instead, everything is neutrally stable.

Such neutral stability would not necessarily be pathological in an idealized physical system, such as a perfect harmonic oscillator, but here it is pathological. All abstractions are simplifications, and here one of the simplifications is the assumption that the prey population is limited only by the predators; in the absence of predators, prey can increase in numbers without bound. Inclusion of any carrying capacity

for the prey, no matter how large or small (as in the second pair of equations in **Box 2**), changes the dynamics completely. The equilibrium becomes stable, oscillations die out, and memory of past perturbations fades with passing time (**Figure 6B**). Another simplification is that predators are never satiated: They consume all the prey they encounter. Inclusion of a more realistic predator response can make the equilibrium unstable. The oscillations converge to a stable cycle of fixed amplitude, again with memory of past perturbations fading.

Thus, this simplest Lotka–Volterra formulation is structurally unstable with respect to important ecological factors. Structurally unstable ecological systems do not commonly appear in nature, so conclusions drawn from structurally unstable models must be used with caution.

Related Effects of Eutrophication

The change in structure from stable equilibrium to stable limit cycle, as described previously, may be induced by changes to parameters of the ecosystem. Eutrophication is enrichment by high levels of nutrients, such as increased phosphorus in a lake or nitrogen in the soil. Eutrophication is one of the principal effects of human domination of ecosystems, and it may affect both their biodiversity and their stability.

Graphical analysis by Rosenzweig and others in the 1970s (Rosenzweig, 1990) showed that stable equilibria in producer–consumer systems were favored when the carrying capacity of the consumer was relatively small. If the carrying capacity of the consumer were higher, the equilibrium would be less stable (less resilient). At a sufficiently high carrying capacity, the system would pass through a structural instability and the equilibrium would lose its stability entirely. Oscillations in producers and consumers would then occur. At even higher carrying capacities, the size of the oscillations would increase, driving both producer and consumer periodically to low population levels, thereby increasing the chance of extinction.

Now, carrying capacity is directly related to the level of resources available. Eutrophication increases these resources, thereby increasing the carrying capacity of the producer. Ironically, the act of providing more food or resource to the producer can lead to its destruction as a result of induced instability. This effect has been called the paradox of enrichment. A common result in observed fertilized terrestrial systems is a reduction in the number of species. Although there can be many reasons for this, loss of stability upon enrichment has been suggested as a contributor (Rosenzweig, 1990).

Spatial Stability

A property that is stable at one spatial scale need not be stable at larger or smaller scales (Levin and Segel, 1985). This was decisively demonstrated in the mid-twentieth century by the mathematician Alan Turing. Turing’s simplest example was a (nonecological) dynamical system operating in two separate cells, optionally with some migration between the cells (**Box 3**). If the two cells are completely disconnected, then there is an asymptotically stable equilibrium that both cells approach. Thus, if the density in either cell is perturbed, it will

Box 3

$$\frac{dx_1}{dt} = ax_1 - by_1 + h - m_x(x_1 - x_2)$$

$$\frac{dy_1}{dt} = bx_1 - cy_1 + h - m_y(y_1 - y_2)$$

$$\frac{dx_2}{dt} = ax_2 - by_2 + h - m_x(x_2 - x_1)$$

$$\frac{dy_2}{dt} = bx_2 - cy_2 + h - m_y(y_2 - y_1)$$

Turing's basic example of diffusive instability. Variables x_i and y_i are densities in cell i . The remaining symbols are constant coefficients, $a=5$, $b=6$, $c=7$, $h=1$, $m_x=1/2$, and $m_y=9/2$ (see **Figure 7**).

Figure 7 Spatial diffusive instability in a two-cell example. The vertical axis is density, or concentration, of two of the variables (x_1 and x_2) for the example shown in **Box 3**. The two cells are isolated until time 4, when a migration corridor between the cells is opened. Isolated, each cell approaches the same stable equilibrium (times 0–4). Connected, this equilibrium is destabilized by migration and the two cells diverge rapidly (times 4–6). Initial conditions are $x_1(0) = 1.13533$, $y_1(0) = 1.1218$, $x_2(0) = 0.864666$ and $y_2(0) = 0.8782$.

return to its equilibrial value (**Figure 7**, times 0–4). However, if there is sufficient migration between the cells, then the equilibrium, though it still exists, becomes unstable. Any random deviation that causes a difference between cells, however slight, unbalances migration and causes a sustained and accelerating net transport toward the cell with the higher concentration (**Figure 7**, times 4–6). This is called a diffusive instability or a Turing instability. An equilibrium that is stable at a point of space can become unstable when its components can diffuse to neighboring parts of the space. This resulting instability can lead to variations and patterns in biodiversity over the landscape, with the resulting patterns being stable.

The opposite can also hold. A system that is unstable in a point of space can become stable, or at least persistent, when extended over a region. Predators clearly coexist with their prey and parasites coexist with their hosts for long periods in nature. However, such coexistence has been difficult to scale

down to the size of experiments. Many of the early experiments on predator–prey and host–parasite systems found them to be unstable at small scales. Confined to a small area, the predators captured all the prey, and then themselves disappeared from the experiment for lack of food (or, analogously, the parasites infected all the hosts and then themselves disappeared). However, as the spatial extent of the experiment was increased, persistence of the system increased dramatically. Ecological models of such systems show a similar behavior (Hassel and Wilson, 1997). Although each individual cell quickly runs to extinction, migration “rescues” empty cells, and the host and the parasite can have a stable average density over a large group of cells. Thus, an equilibrium that does not exist or is unstable in a point of space can be replaced by a stable equilibrium averaged over the entire region.

Something similar happens in ecological systems described by metapopulation dynamics (Hanski, 1997). Individual populations of a species may be separated by distances or barriers that inhibit movement between populations. If movement is strongly inhibited, individual populations may be driven extinct locally by stochastic effects, only to be restored later by propagules from some other population. Despite individual populations going in and out of existence, the portion of local sites occupied at any time can approach a stable equilibrium. This locally nonpersistent system can be both persistent regionally and have a stable regional equilibrium.

Evolutionary Stability

On the ecological timescale, ecological parameters such as birth and death rate are considered fixed. They are taken to be immutable characteristics of the species under consideration. However, ecological systems have many layers of complexity beyond our simple abstractions of them. On the evolutionary timescale, the parameters are malleable through the process of mutation and natural selection. Moreover, species formerly isolated may come into contact either as a result of natural causes or, now with great frequency, through the actions of humans. Both invading species and mutant phenotypes present new parameters that test the evolutionary stability of the system. A condition that is stable with ecological parameters fixed need not be stable when these parameters can change.

How the parameters might change can be seen by examining the growth rate of potential invaders, initially at negligible densities, entering the community at equilibrium. If the growth rate of any phenotype is positive, then the system can be invaded by that phenotype. The resident species, and hence the parameters of the system, are evolutionarily stable only if the growth rate of every potential invader is negative. Originally developed for behavioral systems, this idea is being applied to ecological communities (Geritz *et al.*, 1998), and such work promises to shed light on the properties of invasions and ultimately on the evolution of biodiversity.

Glossary

Community-based conservation Conservation-oriented management of communal or public property by local residents.

Ecosystem management Management of an ecologically defined geographical area as an integrated whole for both sustainable yields of natural resources and maintenance of ecological processes and species populations.

Integrated conservation and development project Project that links biological conservation with human development in a local area or set of areas.

Land ethic Philosophy of proper treatment of lands and the natural communities on them.

Natural resources management Management of natural systems to maintain or provide yields of wood, water, and other resources for people.

Nongovernmental organization An organization that is not an agency or part of a government, typically one that is not-for-profit and not owned by individuals.

Stewardship Management of a thing for someone or something else.

Etymology

The term “steward” has existed for approximately 1000 years. According to the *Oxford English Dictionary*, its early form “stigward” first appeared in manuscripts in the eleventh century. The prefix “stig-” is probably the Old English word for “house or some part of a house.” “Weard” is an Old English word for keeper. A steward is literally a “household-keeper.” This gives the word an interesting kinship with the word “ecology,” coined eight centuries later from Greek words for “house” or “household” and “study.” The steward manages what the ecologist studies.

The essence of the idea of a keeper is one who manages something for someone else. For example, the Old Teutonic root “wardo,” presumably related to “weard,” gave rise to the word “warden.” This word was used in a conservation sense during the Renaissance. A royal act under Edward I in 1543 proclaimed that “The wardeyns shall kepe and susteyne the lands without makynge destruction of any thyng.” In thirteenth-century France, wardo became “garde” and then “guardian” in fifteenth-century England, meaning “one to whom the care and preservation of any thing is committed.” Like his Latinate equivalent, a “custodian,” a “guardian” could manage but not rule: “From that yere ... were al custodyes & gardeyns and no mayres” (Robert Fabyan, *The Newe Chronycles of Englande and of Fraunce*, 1516).

The “household” in “steward” may at first have meant exactly that. The first meaning of “steward” in the *Oxford English Dictionary* is “an official who controls the domestic affairs of a household, supervising the service of his master’s table, directing the domestics, and regulating household expenditures.” However, usage of “stewardship” soon extended beyond the kitchen and pantry. As the “royal households” in England and Ireland became more exalted, “steward” became a title of high office. In early Scotland, the Lord High Steward was the first officer of the king. One such official, Robert the Steward, claimed the throne. As the new ruler of the royal

household, he was no longer its steward, and his epithet changed, founding the royal house of Stuart. On the other hand, a king threatened with the loss of his crown might find it expedient to claim to be in the employ of a still higher authority and therefore to be a steward. Shakespeare had Richard II make this case: “Show us the hand of God, That hath dismiss’d us from our stewardship.” The formal usages of stewardship now include the management of any property owned by someone else.

Some contemporary common usages of “steward” adhere to these formal meanings. People today probably encounter the word steward most often in the person of an airline or ship’s steward, someone in charge of food service on an airplane or ship owned by someone else. Organizations such as The Nature Conservancy employ “land” or “reserve stewards” to manage natural areas. These stewards are paid to manage part of an estate for the owner, which is the organization.

Other common usages of “steward” include the management of intangible things, such as rights or beliefs. A “shop steward” is a union official charged with protecting the rights of a group of employees; a “religious steward” may be a volunteer charged with helping to maintain a faith or church. Stewardship can also refer to the management of things owned by the steward, as long as he or she is acting on behalf of interests greater than his or her own. Currently, the most common use of “steward” in relation to the conservation of biodiversity is for private individuals or companies that agree to abide by special practices designed to protect or restore natural species or ecology on their own lands. A wide variety of national, state, and local governmental and nongovernmental agencies and organizations sponsor programs that recruit private landowners to volunteer as such “ecological,” “environmental,” or “habitat stewards.”

Despite these extensions of the original meaning of “steward,” the concept of stewardship remains distinct from the concept of belonging, on the one hand, and from the concept of domination, on the other hand. Belonging implies

being an equal or subordinate part of a thing rather than managing it. The first premise of stewardship is the competence and right to act on the thing in one's charge so as to produce certain results. Domination, or proprietorship, implies controlling or managing a thing in one's own interests. The second premise of stewardship is that the desired outcomes of management are designed to satisfy interests greater than those of the steward alone. Stewardship is a three-way relationship between a manager, a thing being managed, and the principle or party in whose interests the manager acts.

Rationales

Stewardship can have a variety of rationales. These rationales can be classed as instrumental, if management is viewed as a means to an end, or as intrinsic if management is viewed as an end in itself. For example, the guardian of a child can be considered to be a steward of the child if he or she is taking care of the child for the sake of someone besides the guardian himself or herself. The guardian might be doing so for instrumental reasons, such as because his or her community needed more adults. Alternatively, a guardian might be taking care of a child for intrinsic reasons, such as because he or she believed it to be his or her duty to a deceased parent or because raising a child to realize his or her full potential is intrinsically good. The following sections summarize some of the instrumental and intrinsic arguments for the stewardship of biodiversity and some of the counterarguments to the use of stewardship models as the basis for conserving biodiversity.

Instrumental Arguments for Stewardship of Biodiversity

Ecological stewardship has been justified largely on instrumental or practical grounds. George Sessions (as cited in Oelschlaeger, 1992, pp. 90–130) engagingly categorized types of instrumental arguments for preserving wilderness as a “silo” for storing organisms that might have eventual use; as a “lab” for long-term, large-scale natural experiments and baseline data; as a “gym” with spectacular recreational opportunities; as a “cathedral” for the appreciation of beauty or one's natural heritage; as a “minding animals” zone needed for normal human development; as an “antitotalitarian” object lesson in how to be free and make decisions for oneself; and as a “life-support system” to furnish water, nutrients, and the right mix of gases.

Much of the history of conservation can be viewed as a succession of instrumental schools of ecological stewardship, referred to collectively by R. Edward Grumbine as “resourceism.” Natural forest management has followed instrumentally motivated stewardship models for at least two centuries. Georg Ludwig Hartig, organizer of the Prussian Forest Service, wrote in 1795 that, “All wise forest management must endeavor to utilize as much as possible, but in such a way that later generations will be able to derive at least as much benefit from them as the present generation claims for itself.” This view was embodied in the European concept of a “dauerwald,” a permanent or perpetual forest, generally characterized by uneven-age forestry and selective cutting. Gifford Pinchot, head of the

U.S. Forest Service at its inception in 1905, called conservation “the one great central problem of the use of the earth for the good of man.”

The set of practices referred to as “sustainable development” is based on an instrumental argument for stewardship of ecological systems and natural resources on behalf of all people and their posterity. Herman E. Daly succinctly defines sustainable development as “development without growth.” Its objective, as stated in the 1987 “Brundtland Report” of the World Commission on Environment and Development, is “meeting the needs of the present without compromising the ability of future generations to meet their own needs.” On a more humble scale, this is like passing on the family farm in better shape than you found it, and one of the most resonant arguments for sustainable development is that it is essential for the welfare of one's children. Author Peter Mattheisen has appealed for stewardship of biodiversity because “indifference to the loss of species is, in effect, indifference to the future, and therefore a shameful carelessness about our children.” When Margaret Jacobson and Garth Owen Smith asked Himba pastoralists in northwestern Namibia in the 1980s and 1990s why they wanted to conserve local wildlife, a common reply was so that their children could see them.

Ecosystem management focuses on natural resources management rather than on human development but makes the same argument for environmental stewardship as does sustainable development—that it is beneficial to people in the present and in the future (Johnson *et al.*, 1999). Steven L. Yaffee of the University of Michigan noted that the term “ecosystem management” covers a range of approaches to natural resources management, from “anthropocentric” plans for multiple use of natural resources through “biocentric,” whole-ecosystem management to “ecocentric,” natural regionwide plans. The first approach was codified as early as 1906 in the Multiple Use Sustained Yield Act of the U.S. Congress under Theodore Roosevelt. Whole-system management was in principle implemented by the National Park Service in 1963 when it accepted the recommendation in the “Leopold Report” of its Advisory Board on Wildlife Management, chaired by Starker Leopold, to manage its lands as “biotic wholes.” The statutes that govern the Oregon Board of Forest Lands prescribe a regionwide plan to manage for “greatest permanent value,” defined in a 1998 administrative rule as “healthy, productive and sustainable forest ecosystems that over time and across the landscape provide a full range of social, economic, and environmental benefits to the people of Oregon.”

There is evidence that people in the United States find instrumental rationales for ecological stewardship more convincing than intrinsic ones. As part of a study funded by the U.S. Forest Service Office of Communication, 30,000 on-line news stories about national forests published from 1992 to 1996 were searched by computer for references to benefits in four categories: “recreational,” “commodity,” “ecological,” and “moral/spiritual/aesthetic.” Recreational benefits accounted for about 40% of the citations, commodity benefits for 30%, ecology for 20%, and moral benefits for only about 10%. Recreational benefits tend to translate into local economic benefits and are important not only to people who recreate but also to those who sell to them or tax them. A 1999 report

from the U.S. Department of Agriculture on population and economic growth in nonmetropolitan counties in the contiguous United States from 1970 to 1996 found that growth was strongly dependent on local natural amenities, as measured by an index based on weather, topographic variation, and water surface area. Populations grew by 120% on average in the counties that scored high on the amenity index and only by 1% in the counties that scored low. High-scoring counties also had a threefold higher increase in number of jobs compared to low-scoring ones.

Intrinsic Arguments for Stewardship of Biodiversity

Moral philosophy has provided many intrinsic arguments for the stewardship of species. Concepts of “moral status” have been held to require varying degrees of solicitude for different species depending on their ability to make decisions, be self-aware, feel desire or pleasure or pain, and strive to exist. A being has moral status when it has “moral duties directed to it” by “moral agents,” those “able to deliberate and act in a responsible and answerable way” (Wetlesen, 1999). Some philosophers, such as Plato and Kant, assign moral status only to beings with free will, meaning normal humans. Thomas Regan has argued for moral status for beings that experience emotions and have a sense of their own individuality, meaning normal mammals more than 1 year old and possibly other animals such as birds. Animal rights advocate Peter Singer has proposed sentience, the ability to have conscious feelings of pleasure or pain, as the qualification for moral status.

In addition to the issue of who or what should be accorded moral status, there is the issue of how equal this status should be. One might have equal moral duties toward all things with moral status or greater duties toward some of these things than toward others. Many ethical philosophers accept that persons have equal moral status. As signatories to the Universal Declaration of Human Rights of the United Nations, many nations accept this as well: “All human beings are born free and equal in dignity and rights. They are endowed with reason and consciousness and should act towards one another in a spirit of brotherhood.” Ethical philosophers generally assign nonpersons a lesser moral status. For example, Mary Anne Weaver reasoned that people have a moral responsibility to accept the equal rights of all persons, to avoid cruelty to sentient beings, and to respect all life. Wetlesen (1999) proposed “equal value for moral persons and agents and lesser values for non-persons, in proportion to their similarity with moral persons.”

Stewardship of things that have no moral status can be morally justified on the basis of their importance to things that do have moral status. For instance, it could be held to be wrong to shatter a stalactite because it will deprive other people of the enjoyment of seeing it or wrong to divert water from a pool because it will endanger a fish. In most minds, this provides the only intrinsic justification for stewardship of nonliving things. However, thinkers such as Baird Caldicott elaborate reasons for attributing intrinsic values to wholes, which could apply to ecological systems.

In addition to its instrumental schools, the history of conservation contains a tradition of intrinsic arguments for

stewardship, documented in the writings of John Muir, Henry David Thoreau, David Brower, and others. In 1864, George Perkins Marsh wrote that “Man has too long forgotten that the earth was given him for usufruct alone, not for consumption.” Toward the end of his career in 1949, Aldo Leopold proposed that “A thing is right when it tends to preserve the integrity, stability and beauty of the biotic community. It is wrong when it tends otherwise” and that “The last word in ignorance is the man who says of an animal or plant, ‘What good is it?’” Ecologist Charles S. Elton ventured in 1958 that the real reason for conservation is that “animals have a right to exist and be left alone, or at any rate that they should not be persecuted or made extinct as species.” Robert H. Nelson summed up how environmentalists who justify biological conservation on moral grounds might view things: “To argue for building a dam would be like arguing for the institution of slavery because it was economically efficient.”

Intrinsic arguments for the stewardship of biodiversity have found their way into legal philosophy and animal rights legislation. Roderick Nash (1989) made a case for regarding legal rights for nonhumans as a logical continuation of the progressive enfranchisement of different economic classes, races, and genders of people. Christopher D. Stone raised the question of legal rights for nonanimals in his 1972 essay, “Should Trees Have Standing?” (Southern California Law Review 45(2), republished in 1974 by William Kaufmann, Los Altos). Some natural lands have been set aside for use by wild animals only. Several areas in the Sierra Nevada of California that have bighorn sheep are closed to human entry during most of the year.

Does it make a difference whether the rationale of stewardship of biodiversity is instrumental or intrinsic? Two ways that it might are if one type of rationale is more likely to withstand arguments against conservation or if the two types lead to different ways of managing. It has been widely argued that only instrumental justifications for biological conservation will lead to political action or stand up to conflicting economic pressures. The plant most often cited as an example of why it is important to conserve biodiversity is the rosy periwinkle of Madagascar. Chemicals extracted from this wild plant were discovered to cure childhood leukemia. Others argue that only a belief in the right of species to exist will motivate stewardship of biodiversity since most species have no demonstrable human use or known ecological significance. One interesting possibility is that it takes intrinsic arguments to generate instrumental ones. Officials of the United Nations Commission on Economic Development interviewed in the early 1990s by P. P. Craig and colleagues confided that although they made only instrumental arguments for environmental conservation in their professional work, they privately believed that the real arguments were intrinsic.

Counterarguments against Stewardship as a Model for Conserving Biodiversity

Without necessarily rejecting the idea that it is important to conserve biodiversity, many groups and individuals have rejected the concept of stewardship of biodiversity. Objections have been made to each of the two basic premises of

stewardship: that management of biodiversity is needed and justified and that people should care for biodiversity on behalf of interests greater than their own.

One objection to the idea of managing biodiversity is that it is self-defeating because the essence of the biological world is its wildness. In an essay on "the etiquette of freedom," Gary Snyder (as cited in Oelschlaeger, 1992, pp. 21–39) contrasts the meanings of "natural" and "wild." He argues that managed things may be natural but not wild and that wildness is the world itself. Paul Taylor distinguished the realm of "bioculture," in which husbandry and agriculture may take place, from that of wilderness, in which "noninterference ethics" should prevail. George Sessions (as cited in Oelschlaeger, 1992, pp. 90–130) rejects the model of stewardship for wilderness and admits only that "perhaps some ecologically enlightened version of the 'stewardship' model is appropriate for the bioculture."

A second objection to the idea of managing biodiversity is that it is foolhardy because we do not know enough about wild species and ecological systems to know which actions to take. This objection is supported by past management errors. Human suppression of fires in western North American parks and national forests in which natural fires occur regularly has inhibited reproduction of plant species and reduced the diversity of some forests. Alston Chase argued that ecosystem management has altered wildlife processes in Yellowstone National Park.

These objections to the concept of stewardship of biodiversity can be viewed as cautions about what stewards should do rather than reasons to abandon stewardship altogether. Those who argue against managing wildness do not necessarily preclude protecting wilderness areas from development. Those who argue that humans need more knowledge to manage ecological systems successfully may also argue that the best course is to try to acquire this knowledge through "adaptive management," in which the results from each management prescription are analyzed and used to plan the next. Jack Ward Thomas said that "an ecosystem is not more complicated than we think, it is more complicated than we can think." However, as then head of the U.S. Forest Service, he probably did not mean by this that ecosystem management should be abolished but rather approached with humility. Richard L. Knight has likewise proposed that an appreciation of the complexity of nature and a willingness to learn from mistakes and modify techniques are essential components of good stewardship of biodiversity.

A counterobjection to the notion that human management of biodiversity is foolhardy is that humans now have no choice but to manage natural systems because we already dominate them, foolishly or not. Globally, humans are said to consume two-fifths of the earth's photosynthetic productivity and to have doubled the rate at which nitrogen is being supplied to plants (Vitousek *et al.*, 1997). On some islands and some continents, human influences have been judged to now determine the distributions of species and the risks of extinction of animal populations more than natural factors. Many remaining areas of habitat are too small to maintain their biodiversity naturally. In southern Africa, where elephant populations have been largely restricted to movement within reserves, elephants can multiply to the point at which they

deforest large areas, leading managers to kill elephants to conserve trees. In other systems, humans have eliminated key elements and may have to replace their actions artificially. Short periods of grazing by livestock have been found to promote biodiversity in interior North American grasslands, possibly because the grazing simulates the effects of the great herds of buffalo that formerly wandered the grasslands.

A second counterobjection to the charge of foolhardiness is that humans are an integral part of some ecological systems. Aboriginal burning of savanna in what is now Kakadu National Park in Australia may have been part of the fire regime for 50,000 years. This is clearly long enough for native species to have evolved in response to human-caused fire frequency.

A third objection to human management of biodiversity is that we have no right to be managers, that we stand in relation to other species, not as stewards, but as siblings. The native American writer Black Elk represented his people's belief that "We are of Earth and belong to You. Every step that we take upon You should be done in a sacred manner." In his book *The Green Fuse*, biologist John Harte explicitly rejected the idea of humans as stewards of ecological systems; it is more accurate, he said, to think of nature as the steward of humanity and to call upon humans to be stewards of their own impulses. "Self-Stewardship" is the title of the chapter that deals with stewardship in Vice President Al Gore's book *Earth in the Balance*.

The second premise for the stewardship of biodiversity is that persons should manage it for the sake of interests greater than their own. Many people reject this in favor of the premise that humans rightfully dominate nature and are the rulers and not the stewards of biodiversity. Captain Vancouver is said to have remarked upon seeing the virgin temperate rainforests of his eponymous island that here were enough masts to supply the British Navy forever. The belief that man should rule over nature figures prominently in Judeo-Christian tradition. The Book of Genesis in the Bible records that humans shall "have dominion over the fish of the sea, and over the fowl of the air, and over every living thing that moveth upon the earth." Confusingly, some recent Christian models called stewardship models still portray humans as dominant over the earth (Sessions as cited in Oelschlaeger, 1992). It should be noted that individual Judeo-Christian theologians have long argued the opposite—that humans do not have dominion over other living things. The medieval Jewish philosopher Moses Maimonides wrote, "It should not be believed that all the beings exist for humanity. On the contrary, all the other beings too have been intended for their own sake and not for the sake of something else." According to the contemporary Catholic theologian Thomas Berry, "The earth belongs to itself and to all the component members of its community." In *The Ecology of Eden*, Evan Eisenberg traces these contradictory theological viewpoints back to the biblical injunction to Adam and Eve to both work and protect the Garden of Eden, that is, to have dominion over the organisms but safeguard the divine creation.

A recent legal embodiment of the belief that people can own other life is the extension of intellectual property rights to cover species or aspects of the genetics or metabolism of a species. This principle, upheld by U.S. courts and by international governmental trade organizations, has been touted as an essential economic incentive for the development of biological

and medical technology and as a way to ensure that developing countries and local residents derive benefits from biodiversity. In 1971, the first patent on a genetically engineered organism was granted in the United States to General Electric and its employee, Anand Mohan Chakravarty, for a *Pseudomonas* bacterium into which plasmids from three other bacterial strains had been introduced. The General Agreement on Trade and Tariffs that governs much of world trade contains a Trade Related Intellectual Property Rights agreement that can cover wild species and their products. Even aspects of human biodiversity can become private property. The government of Iceland has debated transferring the intellectual rights to a national database of citizens' genetic information to a corporation.

Throughout history, many societies have held that humans can own individual living things as property, including other humans. Real property rights often include the rights to plants, animals, and minerals on the property. However, it is also usual to recognize that there are multiple interests in real property, that public and private interests are commingled on almost all lands, and that property owners have responsibilities to avoid using their property in ways that harm their neighbors or society. The interests of landowners in the natural resources on their property can be legally balanced against the recreational and environmental interests of the public. On a more moral plane, Aldo Leopold wrote in "The Ecological Conscience" in 1947 that "when a farmer owns a rarity he should feel some obligation as its custodian and a community should feel some obligation to help him carry the economic cost of custodianship."

A final counterargument against stewardship as a model for the conservation of biodiversity is that the most effective basis for conservation is love, which does not involve acting in interests greater than one's own. To explain this argument, it is useful to return to the example of a guardian and a child. Instead of taking care of a child to produce an adult or out of duty or principle, a guardian might do so out of love for the child. Love is neither an instrumental nor an intrinsic rationale; it is not rational and involves no third party or principle in whose interests one acts. Just as many will argue that love of a child leads to the best child care, Wendell Berry has proposed that "love of place" leads people to care for species and habitats. The land ethic propounded by Aldo Leopold (1966) also contains an element of love: "When we see land as a community to which we belong, we may begin to use it with love and respect" and "affection based on utility alone leads to the same pitfalls and contradictions in land as in people."

One practical implication of this view is that the best way to promote the conservation of biodiversity is to take people to see it. One cannot love without at least first sight. In southern Africa, many programs are dedicated to taking children to see wildlife. Courses for "decision makers" run by the Organization of Tropical Studies in Costa Rica discuss arguments for conservation but also take their prominent students to watch sea turtles lay their eggs in the moonlight on a tropical beach.

Contexts

The concept of stewardship has been applied to the conservation of biodiversity in a multitude of forms and with varying

success. This is partly due to the ecological, economic, cultural, political, and historic contexts in which stewardship of biodiversity has been undertaken. These contexts include the mobility of animal populations, disequilibrium in ecological systems, economic incentives and disincentives for conservation, poverty and industrialization, the scale of trade, traditional views of the place of humans in nature, legal systems of land and resource tenure, and the displacement or migration of peoples. Some of these contexts for stewardship are briefly discussed in the following sections.

Ecological Factors

Stewardship requires that the scale of management match the scale of the thing being managed. In the phrase of Kai Lee, there is often a "mismatch of scales" between ecological processes and human societies. For example, many species and ecological processes cross the jurisdictional boundaries that constrain managers. More than 100 species of Neotropical migratory birds breed in North America and winter in Central or South America. Declines in North American breeding populations have been associated with forest losses in Central and South America. Marine organisms with planktonic larvae often disperse widely on ocean currents and depend on long-distance dispersal to maintain local populations. The establishment of new juveniles in marine reserves may depend almost entirely on dispersal from outside reserves. Aerial nitrogen deposition, which occurs on a global scale (Vitousek *et al.*, 1997), is thought to be responsible for replacement of heathland by grassland in The Netherlands. Due to the "openness" of ecological systems, reserves may be, as Mark H. Carr and colleagues suggest, "necessary but not sufficient for conservation."

Ecological fluxes and connectedness complicate the notions of ownership and management. Many species and the resources on which they depend fall into the category of "common pool resources," which have been defined as "those from which multiple independent users cannot be excluded and in which consumption by one user detracts from another's consumption." These include species outside national boundaries, as in international waters, and species on communally owned lands. Models for the stewardship of biodiversity in commons range from international legal agreements such as the United Nations Convention on Marine Law, which assigns states bordering oceans and seas specific rights and responsibilities for their use, to the customary land tenure systems of African pastoralists.

Land stewardship may be more difficult in habitats in which resources are relatively scarce or where natural conditions are unpredictable or rapidly changing. E. Steen observed that cultures in the relatively dry habitats around the Mediterranean have tended to exhaust soil fertility except where there are reliable pulses of water with low salt and high alluvial content, such as along the Nile. Frequent erosion and deposition of soil maintain plant species diversity in highly dynamic habitats, for example, along rivers and on coastal sand dunes, making it necessary to manage for land instability. The prevailing view of ecological systems has shifted from a notion of dynamic equilibrium, in which systems are expected

to tend to reach and return to one steady state, to one of disequilibrium, in which systems are expected to change directionally over time. This makes biodiversity a moving target for management. Some ecological systems switch between alternative states: They may show a nonlinear response to human use, remaining relatively stable until use reaches a certain intensity or cumulative level and then change relatively rapidly, or they may not change back even when use discontinues. This makes it difficult for managers to learn from experience. In habitats in which rare events strongly affect the distribution and abundance of species, managers may need to be “stewards of catastrophe,” preserving or mimicking the potential for major disturbance.

Economic Factors

Among the many economic factors that impinge on stewardship are disincentives and incentives for conservation, degree of industrialization, and trade across ecological boundaries. When land is taxed based on its most lucrative potential use instead of its current use, landholders are more likely to sell or develop their land. Many laws, such as the Williamson Act in California, have been passed to remove this economic disincentive for farmers. Often, farmers agree not to develop their land in exchange for current use valuation of the land for tax purposes. Laws have also been passed to create economic incentives for stewardship of biodiversity. One widely used instrument is the conservation easement, an agreement under which a landowner agrees not to use his or her lands in certain ways in exchange for relief from taxation. The Federal Agriculture Improvement and Reform Act of 1996 created or redirected a set of U.S. Department of Agriculture programs that provide economic encouragement to private landowners to protect wildlife habitats. The Wildlife Habitat Incentives Program provides cost-sharing for habitat improvement, the Conservation Reserve Program pays farmers to fallow cropland under a vegetation cover for a decade, the Wetlands Reserve Program provides conservation easements and cost-sharing for restoration and protection of wetlands for 30 years or more, and the Environmental Quality Incentive Program combines education and technical and financial assistance to help landowners adopt practices that reduce environmental problems.

Economic conditions in developing countries have been linked to poor stewardship of biodiversity in several ways. Poor people in rural areas are likely to depend heavily on local natural resources, and a large proportion of land area is likely to be settled by farmers. Over time and with population growth, use tends to become unsustainable. Governmental agencies are likely to lack the resources to enforce protection of species in nature reserves. Wood and charcoal are a main source of fuel in cities, leading to deforestation for hundreds of kilometers into the countryside, as around Kinshasa in Congo. On the other hand, it is by no means clear that economic development improves stewardship. In central Africa, “de facto” conservation of biodiverse areas by their remoteness and local economic poverty has probably been as effective as intentional stewardship in the region. One hypothesis is that development will tend to improve stewardship of biodiversity

where subsistence resource use is the main cause of its loss, as is probably the case for forests in Madagascar, but not where commercial exploitation is the main cause, as in the forests of Cameroon.

The differences between economic conditions in developing and industrialized countries are often held to require different approaches to stewardship. Conservationists in developing countries largely argue that local rural communities must receive economic benefits from protected areas. This is the basis for the spread of integrated conservation and development projects, which generally link biological conservation within a protected area to human development in the surrounding communities (Wells and Brandon, 1997). These projects are mainly limited to developing countries.

The globalization of commerce has to some extent reversed the mismatch of scales between ecology and society. It is increasingly the case that trade occurs across ecological boundaries. Global trade is often held to threaten stewardship of biodiversity because it makes it more likely that parties using or profiting from resources will live outside the region from which the resources come, and that they will therefore be less concerned about stewardship or constrained by environmental regulations. This is one basis for “bioregionalism,” advocated by Sale Kirkpatrick and others, which counsels that people use only the natural resources from within their ecological region.

Cultural and Political Factors

Human cultures probably differ in their attitude toward stewardship. For example, D. R. Given argued that the Maori have an environmental ethic that emphasizes guardianship and stewardship, in contrast to a European tradition of dominance over nature. He predicted that laws giving the Maori greater control over resource management would help develop a multicultural, ecocentric biodiversity ethic in New Zealand. Others contend that economic factors tend to supersede cultural traditions. Rodrigo Sierra found no recent differences in impacts between three indigenous and three nonindigenous populations in northwest Ecuador, although there had been differences in the past when economic conditions were different. He concluded that the degree of impact of different peoples on natural systems in this region was primarily associated with economic conditions.

Cultural and political factors can result in “incidental stewardship” of biodiversity, achieved as a by-product of management for other purposes. Some of the most effective stewardship of natural habitat in both the United States and developing countries has been incidental. Lands reserved by the U.S. Army for military bases have become Nature Conservancy preserves and parts of national wildlife refuges and National Park Service units. In the western United States, the military was politically able to completely exclude resource extraction over large tracts of land, some of which now constitute the most pristine examples of semiarid habitats in the region. In some areas of Africa and Asia, small groves held sacred and reserved for religious purposes are among the least disturbed forests.

Local political authority over resource and land use has been associated with good stewardship. Al Gore has proposed that “freedom is a necessary condition for an effective stewardship of the environment” and called to witness the environmental degradation in eastern Europe and hazardous waste sites in poor communities with relatively little political power. Secure land tenure is widely regarded as a precondition for effective land stewardship by individuals and communities. In African countries, governmental ownership of wildlife on private or communal land has been blamed for lack of interest in wildlife conservation.

However, a given political arrangement may have opposite effects on stewardship in different economic contexts. The establishment of wildlife management agencies or funds as “parastatals”—governmental bodies that are economically independent of the rest of the government—has promoted wildlife conservation in Kenya and Zambia. In these countries, tourism in some parks and game management areas was generating more revenues for the central treasury than the treasury was providing to the parks largely because the tourists were almost all foreign and could afford to pay large amounts relative to the local economies. Once given political authority to raise and disburse its own revenues, the Kenya Wildlife Service was able to retain gate receipts at Amboseli National Park and share them with the Maasai around the park. During the wet season, the large ungulates in the Amboseli system rely largely on the Maasai lands for grazing, making the cooperation of the Maasai essential for conservation of biodiversity in the park. In Zambia, governmental revenues from European and North American sports hunters were channeled to the park and wildlife service for management, providing hundreds of jobs for local residents in game management areas. In contrast, requiring parks to be economically self-sufficient in the United States, in which the national park service receives more governmental revenues than it generates, would probably lead to a decrease in resources for park management.

Types of Stewards

Almost every possible type of social or political group has undertaken, or purported to undertake, the management of species and habitats on behalf of interests greater than those of the group. The possible stewards of biodiversity include governmental agencies, nongovernmental organizations (NGOs), corporations, local communities, and private individuals. Governmental agencies and NGOs include international, national, and local bodies. They have worked separately and in partnerships of different types of groups. Through legal and political action, classes of citizens have also acted as stewards. The following sections provide examples of these types of stewards and discuss some of their apparent strengths and weaknesses: Are certain types of stewards more effective or trustworthy as guardians of biodiversity?

Governmental Stewards

International governmental agencies exercise stewardship of nature in the form of conventions, declarations, and moral

and financial support for conservation efforts. Through trade agreements and support for development, international bodies have both negative and positive effects on biodiversity. International governmental bodies are uniquely able to enforce stewardship of global ecology such as upper atmospheric conditions and of common pool resources such as marine fisheries and the Antarctic continent. They can finance and lobby for the protection of local sites that are internationally prized.

The most visible international governmental steward of biodiversity has been the United Nations (UN). In 1982, its General Assembly adopted a Charter for Nature that recognized an intrinsic basis for the stewardship of biodiversity:

Every form of life is unique, warranting respect regardless of its worth to man, and to accord other organisms such recognition, man must be guided by a moral code of action. ... Nature shall be respected and its essential processes shall not be disrupted.

The vote was 114 for, 17 abstaining, and 1 (the United States), opposed. UNESCO, an organization within the UN, designates areas of special cultural and conservation interest as Man and the Biosphere Reserves and World Heritage Sites. Most Biosphere Reserves center on existing protected areas, and designation as a reserve is largely symbolic. However, it may have an important educational value by affirming the preciousness of natural places and help inspire support from other sources. The National Natural Landmark program of the U.S. National Park Service is an example of a similar program on a national scale. The United Nations Environmental Programme directly funds conservation efforts and projects.

The “Montreal Protocol” is often cited as a successful example of international governmental cooperation to protect the environment. This agreement banned most release of chlorofluorocarbons into the air. These chemicals can lower the concentration of ozone in the upper atmosphere and increase the amount of cell-damaging ultraviolet radiation that reaches the earth’s surface. Important scientific analysis to support this political agreement was supplied by an international nongovernmental body, the Scientific Committee on Problems of the Environment of the International Council of Scientific Unions. This is an association of professional scientific associations such as the American Association for the Advancement of Science.

International governmental trade and financial institutions such as the World Bank do not have ecological stewardship as their primary goal. The World Bank has supported projects agreed to have been environmentally harmful, notably the Aswan Dam in Egypt. However, World Bank policies formulated during the 1980s explicitly called for conservation of tropical forests. The bank set up an internal environmental review process for its projects and funded the Global Environmental Facility, which gave unusually large amounts of money to conservation projects throughout the world. Some international trade agreements, such as the Convention on International Trade in Endangered Species, have been directed at conservation of biodiversity. On the other hand, international trade agreements such as the North American Free Trade Agreement and organizations such as the World Trade

Organization have been severely criticized for failing to include adequate environmental protections.

Although dedicated primarily to promoting human development, national overseas aid agencies such as the Department for International Development of the United Kingdom or the Gesellschaft für Technische Zusammenarbeiten of Germany have been funding conservation efforts for more than a decade. In the mid-1980s, the U.S. Agency for International Development (USAID) received a specific mandate from the U.S. Congress to conserve biodiversity and tropical forests. As stewards, foreign aid agencies have the advantages of considerable independence from local pressures and enormous buying power in foreign countries. Some of their disadvantages are political inability to provide long-term support for projects or to manage them directly. For example, USAID funds rather than manages projects and expects them to become self-sufficient within 5–10 years.

National governmental agencies that manage natural resources include park, wildlife, forest, fisheries, land management, environmental, and tourism ministries and services. These agencies are stewards inasmuch as they manage the resources on behalf of groups outside the agency. The U.S. Fish and Wildlife Service refers to the National Wildlife Refuges it administers as “stewardship lands.” However, the primary charge of these agencies is often to maximize the economic returns from resource use rather than to conserve biodiversity. Georgia M. Mace characterized the role of natural resource managers in governmental agencies as generally aiming to maximize continuing yields and collect extensive data on a few species rather than assessing management risks to a wide diversity of species. This would tend to make them poor stewards of biodiversity. For example, maximum productivity is generally negatively associated with maximum species richness. On the other hand, governmental agencies have significant advantages as land stewards. They often command relatively extensive resources and manage a large proportion of the natural lands in a country, including most of the large natural areas. Depending on how their professional incentives are structured, managers within agencies may be largely free from personal conflicts of interest with conservation.

Many governmental resource agencies emphasize resource use over biodiversity conservation for both economic and political reasons. In many countries, including the United States, the operating budgets of national forests are tied to the fees paid by companies for logging concessions. This provides a powerful incentive to manage forests for wood production and to focus on a few economically valuable species. The charter of the U.S. National Park Service calls upon it to protect parks for the enjoyment of visitors. Parks experience pressure to manage for maximum continuing yields of visitors and therefore to develop lodging and shops and to focus on species that are appealing and easy to see, the “charismatic megafauna.”

Research institutions and research departments within resource management agencies operate natural reserves throughout the world. The approximately 30 reserves of the University of California comprise the largest system of any single university. The U.S. Forest Service has designated hundreds of Natural Research Areas, often prime examples of distinctive forest types, that are open to research use only. One

goal of the sites funded under the Long-Term Ecological Research program of the U.S. National Science Foundation is to provide baseline data on ecological function and community structure in diverse habitat types that are as little disturbed by humans as possible. An advantage of research reserves is that they are generally completely protected from consumptive use and largely protected from tourism. However, the reserves are mostly small and subject to experimental manipulations such as animal enclosures and vegetation removal and nutrient addition in plots.

Nongovernmental Organizations and Communities as Stewards

Conservation land trusts, NGOs that purchase land or the development rights to land for the express purpose of maintaining it in an undeveloped state, are likely to have the conservation of species or habitats as their primary goal. Another advantage of land trusts relative to governmental agencies seems to be that they are able to act quickly to acquire habitat in immediate threat of development. The Nature Conservancy is the largest private land trust for natural lands in the United States, with more than 10 million acres of reserves throughout the country. One of its mottos, “the last of the least and the best of the rest,” epitomizes its dual objectives to prevent the extinction of rare species and to conserve whole natural communities and ecological systems. The first objective requires a large number of reserves, some of which may be very small, for example, if the species of concern is a grass. The second requires large reserves, which have to be fewer in number for reasons of cost and availability. Local land trusts have also played important stewardship roles. Starting in the early 1900s, the Save-the-Redwoods League purchased a significant proportion of the remaining old-growth forests of the coast redwood, *Sequoia sempervirens*, which the trust eventually deeded to the government for parks. A disadvantage of land trusts as stewards is that they are rarely able to purchase large areas and generally control only a small proportion of the natural lands in an area. According to the Land Trust Alliance, local land trusts owned about 0.002% of land in the United States in 1999.

A highly controversial type of steward of biodiversity is the local community, the set of human residents in a place. “Community-based conservation” is an important option in societies in which a large proportion of lands are owned or customarily used by communities as a group. It is viewed as an alternative both to the establishment of protected areas that exclude consumptive uses of natural resources by local residents and to natural resources management by governmental agencies. During the 1980s and 1990s, many projects were established to encourage local communities to assume or resume the major responsibility for local environmental stewardship, especially in the developing countries of Africa and Asia. Sets of these projects have been reported on in books edited by Western *et al.* (1994), Mark Poffenburger, and others and in networking organs such as the Forest, Trees and People Newsletter (<http://www-trees.slu.se>). Two of the best known examples in Africa, the CAMPFIRE project in Zimbabwe and the ADMADE project in Zambia, have given varying degrees of

authority for local wildlife management to communities. Community-based forest management has become particularly widespread in India. In the late 1990s, the Van Gujjars, a forest-dwelling pastoral tribe in Uttar Pradesh, proposed to resolve their objections to the establishment of the proposed Rajaji National Park by taking responsibility for forest management in the park.

Reasons cited for turning to community-based conservation are that it is morally right, that local people have expert, "indigenous knowledge" of local species and habitats, that local people have lived in harmony with local nature for centuries, that traditional indigenous populations use a wide variety of wild species and thus have a practical incentive to conserve biodiversity, and that management by governmental agencies or in nature preserves in the area has failed to prevent habitat degradation. The Dayak groups of central Kalimantan in Borneo are reported by W. de Jong and others to provide successful examples of ethnoconservation; the Dayaks have manipulated the forest to increase productivity of species they use without reducing species diversity or simplifying structure.

One of the main reasons for doubting the efficacy of communities as stewards is the world history of environmental degradation. O. M'Hirit concluded that peoples around the Mediterranean have generally harmed their local forests and that only in the twentieth century has there been effective forest conservation in the regions. In 1957, A. Starker Leopold took a dark view:

It is surprising that in the long history of man's conquest of the earth there is no evidence of sustained effort on the part of any people to preserve native landscape for its own sake, until our national park system began to take form late in the nineteenth century.

The consensus at the end of the 1990s was that local communities sometimes do and sometimes do not make effective stewards of biodiversity. Communities of recent immigrants in tropical rainforest tend to cause extensive deforestation because they want cleared land for crops and livestock. Even long-settled, traditional societies do not always use sustainable practices; a recent study concluded that hunters from the Piro people in the Peruvian Amazon make no attempt to conserve species vulnerable to overhunting. Practices may be sustainable only as long as human population density remains low and may change when economic and social conditions change. In a 1999 essay on community-based conservation projects in Africa, J. D. Hackel concluded that they tended to lack clear rules for the protection of local ecology and plans for what to do if conservation goals were not met. In both developing and industrialized countries, local communities may have a limited capacity to ask key questions about conservation values or to provide potential answers and limited time or will to bring issues before the public and decision makers. Others believe that community-based conservation has rarely been properly tested because governments have failed to devolve the authority over resources to communities at the same time that they have decentralized the responsibilities for resource conservation.

A different definition of a community is the set of people that have interests in a thing. In this sense, class actions by

citizen groups and lobbying and public education by conservation organizations on behalf of their members are also forms of community-based conservation. The political and legal systems in the United States provide a direct route for stewardship by citizen groups through referenda and class action suits. An example of stewardship by class action is the work in the 1990s of the Mono Lake Committee in California to prevent Los Angeles County from diverting water from the streams that flow into this large desert lake. Diversion threatened, among other things, to allow coyotes to walk out to the nesting sites of birds on islands in the lake. The Sierra Club is credited with having dissuaded the U.S. federal government from creating a reservoir in the Grand Canyon in Arizona. The club's public advertising campaign asked "Would you flood the Sistine Chapel to get a better view of the ceiling?" Duck hunters are said to be largely responsible for motivating governmental protection of wetlands, which are now, under the RAMSAR convention, the first globally protected habitat type.

Such "community-of-interest-based conservation" can have the advantage of a longer economic view but the disadvantage of pitching legal and sometimes corporeal battles. The controversy over protection of old-growth Douglas fir forests in the Pacific Northwest, in the name of the northern spotted owl, pitted local logging interests against national conservation ones. According to one estimate, the protection plan that was adopted should result in economic gains of about \$110 billion versus losses of only \$32.5 billion. However, the losses are concentrated within the region, whereas the gains are spread throughout the country.

To avoid such battles, a broader community-based approach to conservation has been advocated based on the notion of "stakeholder rights." Stakeholders are all parties with interests of any sort in a given thing, be they economic, political, cultural, moral, or personal. One formulation of this "community-of-different-interests-based conservation" is to provide a forum for stakeholders to produce a common management plan for an area. For instance, the town library in Quincy, California, became a neutral meeting place for local environmentalists and loggers, who produced a plan for an adjacent area of national forest. To the surprise of many outside the "Quincy Library Group," the plan called for relatively intensive harvests, and its adoption by the Forest Service was challenged in court. Truman Young argued that many major conservation successes of recent decades, such as the international bans on whaling and ivory, have essentially rejected current economic stakeholder rights.

Private Companies and Individuals as Stewards

Private companies have also been engaged as stewards. One strategy has been to set up certification programs for commercial products or services. Companies or their taxes pay an independent body to certify that a product has been produced in an environmentally sound way. The expected benefit to the company is that environmentally concerned consumers will buy the product. A well-known certification program is run by the Forest Stewardship Council, an international NGO founded in 1993 "to support environmentally appropriate, socially

beneficial, and economically viable management of the world's forests." The council accredits and monitors certification bodies for forest products. Certified products may carry the council's logo. A newer, Marine Stewardship Council aims to perform an analogous function for marine fisheries.

A second strategy has been to encourage private companies to support in-house conservation projects. The nonprofit Wildlife Habitat Council coordinates a program that enlists corporations to voluntarily manage for wildlife and biodiversity protection. Participants account for about 120,000 ha in the United States. In a survey of benefits to corporations at 164 sites, as reported by H. Cardskadden and D. J. Lober, most respondents believed that the program had improved employee morale (95% of respondents) and relations with environmental groups (72%) and the local community (64%). Half of the respondents reported that programs had resulted in annual cost savings, such as through waste reduction. In the absence of scientific monitoring, there was no indication of whether there had been any benefits to wildlife or biodiversity. This is a common problem in many nongovernmental stewardship programs.

By far the most common current use of stewardship in relation to conservation is for programs in which individual private landowners serve as stewards on their own lands, often with economic incentives, technical assistance, or just moral support provided by government or NGOs. The Saskatchewan Wetland Conservation Corporation provides land management advice and a certificate of appreciation to owners of native prairies who make a Voluntary Stewardship Agreement to protect their land from development. The Massachusetts Forest Stewardship Program, run by the state government, shares the costs of habitat improvement for wildlife and rare native fish with private owners of non-industrial woodlands of 10–1000 acres. The Georgia Endangered Plant Stewardship Network of the State Botanical Garden of Georgia trains school classes to propagate rare and threatened wild plants. The Pesticide Environmental Stewardship Program of the U.S. Environmental Protection Agency helps pesticide users to write and implement strategies for pesticide risk reduction.

One reason for appealing to private landowners to serve as stewards of their property in the United States is that development of private land is a significant cause of species decline. In 1998, the Wilderness Society estimated that conversion of private land for commercial and residential development was at least partly responsible for population losses in 35% of the 1880 imperiled plants and animals in the United States. According to Richard L. Knight, "unchecked conversion of U.S. private, open lands to human-dominated development is causing a simplification of our native biodiversity." In some regions, such as northern New England in the United States, most of the lands with natural or seminatural vegetation are privately owned.

An objection to relying on private landowners as stewards is that private landholdings are generally small compared to public ones and cannot accommodate large-scale ecological needs. Remote imaging of land use has documented that habitat patches may tend to be smaller on private than on public lands. This objective can in some cases be partly met by cooperation between landholders. In about 1986, local

landowners in southern Vermont formed the Newfane Wildlife Habitat Improvement Group to plan together for wildlife management. In 1999, the group included more than 50 properties and 7000 acres in three towns. However, the total amount of land in the United States under the protection of voluntary agreements by private landowners is also small—just 0.02% of total land according to a 1999 article by Keith Wiebe and colleagues.

As the previous examples of stewardship on private lands suggest, stewardship is often undertaken through partnerships between public agencies and private parties. This is just one sort of "cross-boundary stewardship"—coordinated land management by multiple stewards, often of different types (Knight and Landres, 1998). Many integrated conservation and development projects are organized as partnerships among governmental agencies, NGOs, and local communities (Wells and Brandon, 1997).

A major advantage of cross-boundary stewardship is that it allows for land use to be "not separate but not equal," to have a diversified portfolio of stewardship types arranged side by side within ecological regions. Arguments for zoning as an alternative to multiple use are not new (Sessions as cited in Oelschlaeger, 1992, pp. 90–130). In 1971, Eugene Odum and John Phillips proposed a landscape of urban-industrial, production, and protection zones. The Biosphere Reserve concept promoted by UNESCO since 1980 envisions protected areas surrounded by an inner zone of human use unlikely to impact the protected core and an outer zone of unrestricted use. Some species do require protected areas in which there is virtually no human impact. A recent analysis of conservation versus human land use by Kent Redford and B. Richter indicated that only extremely limited and largely nonextractive use will protect all components of biodiversity. However, as Sara Vickerman argued, biodiversity cannot be conserved on reserves and with regulation alone (*Defenders of Wildlife*, 1998). A managed landscape can support important elements of biodiversity while meeting human needs. Significant components of biodiversity can and must be under the stewardship of private landowners.

The relative effectiveness of different types of stewards in conserving biodiversity seems to increase with the total amounts and individual sizes of the land areas they manage, the economic and technical resources they command, their independence from conflicting economic pressures and political constraints, the degree of authority they can exercise, and how close their primary objective is to conserving biodiversity. No one type of steward has greatest effectiveness in all these regards. Since it is also true in many landscapes that no one type of steward is responsible for enough land to ensure the conservation of biodiversity, it appears that a mix of stewardship types, arranged side by side in a landscape, is necessary and desirable.

Glossary

Amphibians are tetrapod vertebrates They differ from the other tetrapods (the reptiles, birds, and mammals) in that their eggs are anamniotic; they are relatively simple and are enclosed in a jelly capsule.

Anamniotic Eggs are not surrounded by the complex membranes that distinguish the amniotic eggs of reptiles, birds, and mammals.

Cloaca The common chamber in which the reproductive, excretory, and digestive tracts of amphibians unite before exiting the body.

Metapopulation A group of local populations among which individuals migrate relatively frequently; however, the rate of migration is slow enough that the populations fluctuate independently.

Paedomorphosis Reproduction while retaining at least some larval characteristics.

Tetrapods The terrestrial vertebrate classes amphibians, reptiles, birds, and mammals, so named because they primitively possess four legs.

The Evolutionary History of Amphibians

Amphibians first appeared during the Late Devonian, about 360 million years ago (Ma). There is a general consensus that all amphibians shared a common ancestor, a sarcopterygian (fleshy-finned) bony fish in the class Osteichthyes. All sarcopterygians have paired fins with limb-like bones, and many exhibit other anatomical features, such as lungs, that ally them with the tetrapods. It is not likely that either of the extant groups of sarcopterygians, the dipnoans (lungfishes), and crossopterygians (lobe-finned fishes), contained the ancestor of the amphibians. The earliest major radiation of terrestrial vertebrates occurred during the Carboniferous Period (*ca.* 335 Ma). By the end of the Triassic, about 200 Ma, nearly all of the large ancestral amphibians were extinct. The subclass Lissamphibia, the modern amphibians, appeared during the Triassic and is the only group that has survived to the present.

The ancestry of modern amphibians is poorly understood because there is a sparse fossil record linking primitive amphibians to the three modern orders. The earliest fossil Lissamphibian is *Triadobatrachus massinoti* from the early Triassic, about 230 Ma. *Triadobatrachus* is similar to the modern frogs but is not considered to belong to the order Anura. The Anura (frogs) and Gymnophiona (caecilians) appeared during the early Jurassic (about 190 Ma), whereas the Caudata (salamanders) appeared in the Middle Jurassic, 170–150 Ma. Although the fossil evidence is sparse, phylogenetic analyses of shared derived morphological characters and of molecular characters strongly suggest that the Lissamphibia share a common early amphibian ancestor and that the Lissamphibia and the amniote tetrapods (reptiles, birds, and mammals) originated from different early amphibians. It is possible; however, that the Lissamphibia is a polyphyletic group, with one or more of the modern orders having an independent origin from the subclasses Temnospondylia or Microsauria.

Historical Biogeography and Current Diversity of Modern Amphibians

Modern amphibians are found in all continents except Antarctica. However, the three modern orders show disparate patterns of fossil and recent diversity that are associated with their different histories on the landmass of Pangaea and subsequently on landmasses associated with Gondwana and Laurasia. The evolution of salamanders is linked closely with landmasses derived from Laurasia. All fossil and living species occur in the Northern Hemisphere, with the exception of the lungless salamanders (family Plethodontidae) which invaded South America when the isthmus of Panama completed the connection between North and South America. In contrast, the caecilians and most frogs are associated predominantly with the southern Gondwanan landmasses. The caecilians occur throughout the tropics, except in Madagascar and to the east of Wallace's Line in Australasia. They are the least diverse group of living amphibians, with five families and 188 species, although their highly cryptic nature suggests that many species may remain to be discovered and described. The greatest diversity of species occurs in northern South America and Central America. Frogs are the most widespread of the three orders. Although the breakup of Pangaea probably isolated salamanders on the Laurasian continents and many groups of frogs on the Gondwanan continents, several clades of frogs have dispersed to all continents that support amphibians.

Frost *et al.* (2006) proposed a sweeping revision of the taxonomy of amphibians at all levels. Many aspects of their proposals are still being actively debated. To make it easier to find more information on taxa that may be of interest and relate the basic facts presented here to the broader literature, we have largely retained the traditional scheme. There are now more described species of amphibians than there are of mammals (Stuart *et al.*, 2004; Table 1). More than 600 salamander species are currently known in 10 families, with the highest diversity found in North America. One family, the

Table 1 Richness of modern amphibian taxa

<i>Taxon</i>	<i>Families</i>	<i>Genera</i>	<i>Species</i>
Anura	33	354	6012
Caudata	10	59	608
Gymnophiona	5	33	188
Total	48	446	6808

Plethodontidae of North and South America, contains more than half the known salamander species.

The frogs are placed in 25 families, and more than 6000 species are known, approximately 80% of which are in tropical regions. Roughly 1000 species have been described since the first edition of this encyclopedia, and estimates suggest that another one to two thousand species remain to be described. The greatest diversity of frogs occurs in South America, but other tropical areas such as Southeast Asia, New Guinea, Madagascar, and central Africa also have highly diverse frog faunas.

Four of the five most diverse frog families, the Hylidae, Ranidae, Bufonidae, and Microhylidae, are each found across several continents – distributions that reflect successful dispersal and long evolutionary histories. The most speciose family is the Leptodactylidae, which is restricted to South and Central America and contains 22% of living frogs. It contains the genus *Eleutherodactylus*, which was the most diverse vertebrate genus with more than 550 species until recent revisions created many new genera from many of its species.

Basic Morphology and Functional Anatomy of Modern Amphibians

All modern amphibians have complex glandular skins and all but caecilians lack scales. Their skins are kept moist by the secretions of mucous glands, whereas granular glands produce a variety of toxins that serve to deter predation and also produce a variety of antimicrobial peptides that deter microbial infections. They shed their skins periodically and usually consume them as they are shed. Their color patterns are produced by xanthophores, iridophores, and melanophores. Many species are able to alter the shape of pigment cells and the distribution of pigments within them and can rapidly change color.

The eyes of most species contain photoreceptors of several types, probably giving at least limited color vision, can be covered by moveable eyelids, and focus by moving the lens using ciliary muscles. Many frogs and salamanders have a wide binocular field of vision and have a good depth perception. Many species use olfaction in the detection and capture of prey and have well-developed olfactory systems and Jacobson's organs. Larval amphibians and the adults of many aquatic species have lateral line systems. Amphibians have no external ears; their tympanum (when present) is at the surface of the body. The middle ears have a columella bone (also found in reptiles and birds and modified in mammals), which transmits vibrations from the tympanum to the inner ear. In anurans, there is a second bony element in the middle ear, the operculum, which can be engaged by muscular contractions,

and modifies hearing to increase the reception of low-frequency sounds.

Most terrestrial amphibians respire (in part) with lungs, and have largely separate pulmonary and systemic blood circulations. Their hearts typically have three chambers – two atria that receive blood from the body and the lungs and one ventricle that serves to pump blood to the lungs and the body. Although the ventricle is usually single, a combination of partial septa and the high viscosity of blood reduce mixing of the blood streams flowing to the lungs and the remainder of the body. Many species carry out a considerable fraction of gas exchange across the moist skin; for the lungless salamanders (family Plethodontidae) this is the primary mode of respiration.

The kidneys of amphibians function in maintaining water and ionic balance. In species with aquatic larval stages, most water and ion balance needs are reversed at metamorphosis; the freshwater larvae must cope with a hypo-osmotic environment, to which they lose ions and from which they gain water, whereas the terrestrial stages must cope with rates of evaporative water loss that are typically high because of their moist skins. Aquatic individuals tend to excrete dilute solutions of ammonia, whereas terrestrial animals excrete more concentrated solutions of urea, although no amphibian excretes fluid urine that is more concentrated than the blood plasma. Water uptake in most amphibians does not involve drinking but is accomplished by active or passive transport of water across the skin.

Amphibians are ectotherms, relying on the external environment as a source of body heat. All aquatic forms and many terrestrial forms are also poikilotherms or thermoconformers, with body temperatures that do not differ from their environments. Some species control their body temperatures to some extent by selecting microhabitats that provide appropriate temperatures, and some species of frogs periodically increase their body temperatures by basking in sunlight. The ability of many terrestrial amphibians to thermoregulate by basking is limited by their need to conserve water while maintaining a moist skin. However, many species of frogs have developed mechanisms that allow them to increase their resistance to evaporative water loss. Some species of frogs and salamanders can be active at temperatures approaching 0 °C, whereas others can tolerate body temperatures well above 40 °C. Some temperate species can survive exposure to temperatures below 0 °C by supercooling. A few species can survive partial freezing by a combination of ice-nucleating proteins that encourage freezing of extracellular fluids and high intracellular glucose concentrations that prevent intracellular water from freezing and keep cells from dehydrating.

Special Features of Caecilians

Caecilians are aquatic and burrowing animals that superficially resemble large earthworms. Adults range from approximately 10 to 150 cm in length. They have elongate bodies with distinct annuli, which are grooves delineating their body segments. They are limbless, and their tails are reduced or absent. Their eyes are reduced and are covered by skin. They are unique among the Lissamphibia in possessing

dermal scales, which occur in the annuli of some species. Their skulls are heavily ossified and completely roofed. Caecilians possess a unique chemosensory organ, the tentacle, which extends a short distance from the surface of the head, emerging from a skull opening between the eyes and the nostrils.

Special Features of Salamanders

Salamanders are typically four-limbed animals with relatively long tails. They superficially resemble lizards but lack epidermal scales and claws. Salamanders range from about 30 mm to 2 m in total length. Their limbs are relatively small and are reduced or lost in some terrestrial and aquatic species. Their skulls typically show the loss of many bony elements. Salamanders lack external ears and, with the exception of weak distress calls in some species, do not vocalize. The most diverse group of salamanders, the Plethodontidae of the Americas, is lungless. Salamanders of many groups exhibit various degrees of paedomorphosis, which in some species is facultative, allowing them to exploit high-quality aquatic environments while retaining the option of a terrestrial stage. Salamander larvae are carnivorous and usually have well-developed external gills.

Special Features of Anurans

Anurans are invariably four-limbed, and terrestrial juveniles and adults completely lack true tails. Adults range from about 1 to 30 cm in length. Their hind-limbs and feet are greatly elongated. The radius and ulna of the forelimb and the tibia and fibula of the hindlimb are usually fused. There are no more than nine trunk vertebrae, and most modern frogs lack free ribs. The caudal vertebrae are fused into a rod-shaped urostyle that is associated with the elongate pelvis. Most of these features are probably the result of adaptation for light weight and strength for jumping and show interesting convergences with similar adaptations in birds. The lightweight skulls of frogs are large relative to their body size and lack many bones. All but one species lack teeth on the dentary bone of the lower jaw. The tongue is attached at the front of the mouth in most species and is flipped forward rapidly to capture prey. The ears of frogs often have external tympanic membranes.

The skins of frogs depart from the usual amphibian pattern in several ways. Some species have additional types of glands: lipid glands which secrete lipids that reduce rates of evaporative water loss or breeding glands that produce sticky secretions which adhere the male to the female during amplexus. Skin lipids and other as yet poorly understood modifications of the skin allow some frogs to achieve rates of evaporative water loss as low as those of some lizards. Frogs also have distinct differences between their dorsal and ventral skins. The ventral skin usually has fewer granular and mucous glands, and many terrestrial species have an area called the pelvic patch in which thin and highly vascularized skin can be exposed. Water uptake from substrates via the pelvic patch is the primary means by which almost all species of frogs obtain water. Burrowing desert frogs of several lineages form cocoons

by repeatedly shedding their skins and retaining the shed layers to reduce evaporative water loss while they are buried.

Frogs have a variety of adaptations to structures other than the skin for maintaining water balance. Most species store copious quantities of dilute urine in the bladder when water is available and withdraw water from this pool to replace evaporative losses. Desert species and species that inhabit brackish water can allow high concentrations of urea to accumulate in the body fluids. A few species can excrete nitrogenous wastes as uric acid, which minimizes the water lost when it is excreted.

Reproductive Biology and Life Histories of Modern Amphibians

The typical life history of the Lissamphibia includes a complex life cycle in which eggs are deposited in freshwater habitats, where larvae grow and develop, eventually metamorphosing into terrestrial juveniles and leaving the water. Although this is a common pattern found in all three modern orders, it is far from universal. One of the major features that set amphibians apart from the remainder of terrestrial vertebrates is their extremely wide range of life histories and modes of reproduction, many of which occur in all three extant orders (Duellman and Trueb, 1986). The presence of a wide range of life histories and reproductive modes suggests that the typical amphibian life cycle does not reflect a failure to adapt to the terrestrial environment but rather serves as an adaptation that allows female amphibians to produce very large numbers of eggs with a small investment in each and to exploit freshwater habitats for larval growth and development.

Caecilians

Limited observations have been made on the reproductive biology of caecilians and very little information on their courtship behavior is available. It appears that fertilization is internal via protrusion of the male cloacal wall. Although vocalizations have been reported for some species, it is not known if they are linked to reproduction.

Caecilians are oviparous or viviparous. In viviparous species gestation may take up to a year with reproduction occurring only every 2 years, and nutrition can be supplied to the young within the oviduct. Oviparous species lay terrestrial eggs but the larvae can be aquatic or can complete development within the egg. Oviparous caecilians produce more offspring than viviparous species. In oviparous species, parental care of eggs is common.

Salamanders

Many salamanders conform to the typical amphibian complex life cycle. Most produce aquatic eggs and larvae, which metamorphose into terrestrial juveniles. As in the frogs, there is a great deal of variation beyond this basic mode. Larval salamanders are relatively similar to adults; this has allowed species belonging to several groups to evolve the ability to

reproduce while retaining larval characters, either facultatively or obligately.

An example of the complexity and variability of salamander life histories is the life history of red-spotted newts (*Notophthalmus viridescens*, family Salamandridae). Their life history begins with aquatic eggs which hatch into aquatic larvae. The larvae typically develop within one summer and metamorphose into a morphologically distinct terrestrial juvenile stage, the eft. The eft stage last from 1 to 8 years, depending on temperature and food availability. Efts undergo a second transformation into adults, which then return annually to water to breed. Larvae that encounter very favorable conditions and grow rapidly can retain some larval morphological characteristics, remain permanently aquatic, and reproduce as paedomorphic adults. Larvae that encounter slightly less favorable conditions can bypass the eft stage and metamorphose directly into the adult morphology.

Courtship in salamanders can be quite elaborate, incorporating chemical, visual, and tactile cues. During the breeding season males of aquatic species can develop enlarged fins and become more brightly colored. There may be other morphological changes to the head glands, tooth structure, musculature, and skin during the breeding season. Many salamanders have specialized glands that secrete compounds used as olfactory signals during courtship.

Salamanders have internal or external fertilization. External fertilization involves deposition of the sperm on the egg mass. Salamanders with internal fertilization either transfer sperm directly from male to female or exhibit a unique form of sperm transfer in which a bundle of sperm (the spermatophore) is deposited by males. The spermatophore is picked up in the female cloaca and stored in a special structure in the cloaca, the spermatheca. The stored sperm can remain viable until ovulation, which may occur from a few days to 2.5 years later. In live-bearing salamanders the sperm enters the oviduct, in which the eggs are internally fertilized.

Both male and female salamanders of some species exhibit parental care (Figure 1(a)), although it is practiced mostly by terrestrial breeders and may serve to protect the eggs from predation, fungus infection, and desiccation. Adults attend clutches for up to 9 months. In a few species communal clutches are attended by aggregations of females, and eggs are fertilized by many different males.

Anurans

The most common reproductive strategy in frogs involves a complex life cycle with externally fertilized aquatic eggs which produce highly specialized larvae – tadpoles. The tadpoles grow and develop for some period in the water and then undergo a radical metamorphosis and emerge as terrestrial juvenile frogs. However, frogs have evolved a remarkable variety of reproductive strategies, most involving a trend toward protection of eggs and larvae from the hazards of the aquatic environment. Pough *et al.* (2004) described 29 combinations of egg deposition sites, including still water and fast-flowing water, terrestrial nests, and on or in the body of the male or the female, and they also described tadpole development, ranging from the typical free-swimming feeding larva to direct

development inside the oviduct. Because amphibian eggs lack a water-resistant shell, the greatest diversity of reproductive modes occurs in the humid tropics where eggs can survive for long periods in the permanently moist terrestrial environment. Complex behaviors including egg guarding and embryo transport (on the dorsum, in specialized pockets or pouches, in the mouth, and in *Rheobatrachus* species in the stomach), and unusual morphological structures such as skin pockets to provide protection for developing embryos, are associated with many reproductive modes. Many separate lineages of anurans have evolved direct development, bypassing the aquatic larval stage. Most direct developers have some form of parental care of the eggs. Several species bear live young, and at least one of these, *Nectophrynoides occidentalis*, actually provides oviductal nutrition to its developing embryos.

In tropical regions where conditions for reproduction are favorable throughout the year, breeding can be unseasonal, and females may lay multiple clutches in 1 year. In more temperate or high-altitude regions breeding is typically strongly seasonal, occurring only during short periods of the year when temperature and rainfall reach critical levels. Under these conditions females generally lay only one clutch of eggs each year.

Male frogs vocalize mainly to attract mates (Figure 1(b)) and to advertise their presence and sometimes their status to other males. Calls are species-specific and females typically respond only to males of their own species. Males of most species possess a single or double vocal sac, which serves as a resonator and in at least some species as a sound radiator. Vocal sacs also conserve energy by allowing passive reinflation of the lungs as the vocal sac contracts after a call. Some male frogs, such as the Australian torrent frog (*Litoria nannotis*), lack a vocal sac but can still produce a surprisingly loud call. Environmental conditions such as temperature affect vocalizations. At colder temperatures, notes and pulses are produced at slower rates, but the length of the call increases. The dominant frequencies in the calls of most frogs are lower than 5000 Hz, although those of some small species are higher. Within species, variation in the dominant frequencies, pulse rates, and durations of calls often reflects male body size; therefore, the call may indicate male quality as well as male location. Females of many species use these characteristics to choose their mates from among competing males. Males vocalize from species-specific locations, which can be in water, on or beneath the ground, in vegetation from near ground level to high in trees, and even under water (several species including African clawed frogs, *Xenopus*).

Female frogs do not have a vocal sac and very few vocalize. Some female frogs produce a scream when distressed, and reproductively active females of some species call in response to male advertisement calls. Females of a few species call in other contexts, such as territoriality and during mating.

The posture of frogs during the fertilization of eggs is called amplexus; in most species this involves the male grasping the female from above (Figure 1(c)). The exact posture adopted depends on the morphology and relative size of the male and female. The two most common positions involve the male grasping the female in front of the back legs (inguinal amplexus) or the front legs (axillary amplexus). Amplexus is aided in many species by specialized patches of skin called

Figure 1 (a) A black-bellied salamander *Desmognathus quadromaculatus* guards its eggs (removed from (and replaced in) a small stream, Appalachian Mountains). (b) A male Australian desert treefrog, *Litoria rubella*, produces an ear-splitting call with the aid of its balloon-like vocal sac. (c) Spike-nosed frogs, *Litoria prora*, from New Guinea, in amplexus. The function of the rostral (nose) spine is unknown. (d) A suctorial tadpole of the Australian treefrog *Litoria nyakalensis*. The upper and lower jaw sheaths, surrounded by keratinized teeth and oral papillae set in an oral disc, are clearly visible. These tadpoles use their large ventral oral discs as suckers to attach to rocks in fast-flowing rain forest streams.

nuptial pads on the forelimbs of males. Pairs remain in amplexus whereas the male sheds sperm onto the eggs as they are released by the female. Fertilization in nearly all frogs is external but several species accomplish internal fertilization by cloacal apposition. The frog *Ascaphus truei*, commonly called the “tailed frog”, breeds in fast-flowing streams of the North-west of North America and carries out internal fertilization using the tail, which is actually an intromittent organ formed from an extension of the male’s cloaca.

Ecology and Functional Morphology of Larval Amphibians

Caecilians

Relatively little is known about the larvae of caecilians. They are more similar to adults than are those of frogs or salamanders. Externally, they closely resemble adults but have gill slits and fins. Free-living caecilian larvae have external gills and a lateral line system. Their mouth and dentition resemble

those of adults. They lack the tentacle organ that appears on the head of adults; this appears at metamorphosis.

Salamanders

Salamander larvae are much more similar to adults than are the tadpoles of frogs. Larval salamanders have external gills that are not completely covered by an operculum. Some embryonic salamanders have paired lateral projections from the head called balancers; in some species these persist for a short period following hatching. Most species possess well-developed fore- and hindlimbs through most of the larval period. Their bodies are laterally compressed compared to those of adults, and their tails are also relatively thinner and deeper. Their skins contain lateral line organs (neuromasts) and are thinner and less glandular than those of adults. Their dentition is different from adults, and their tongues are rudimentary. Their eyes lack lids. Larval salamanders are almost all carnivorous, usually feeding on zooplankton and larval insects. The larvae of larger species can also feed on small vertebrates. The larvae of some species have alternative morphologies; the

typical morphology is usually a planktivorous carnivore, but when conditions are favorable some individuals develop relatively larger heads and more powerful jaws, adopting a “carnibal” morphology that allows them to prey more effectively on small vertebrates, including conspecifics.

As in larval frogs, there is considerable variation among and within species in rates of larval growth and development. Both the minimum and the maximum development rates for salamanders are slower than those for frogs. Salamanders can take from 6 weeks to 5 years to complete larval development. Within species, rates respond to both temperature and food availability, and salamanders have the additional option, apparently not available to frogs, of changing the relative rates of development of somatic and reproductive structures so that they mature sexually without losing all larval characters.

Anurans

The tadpole larvae of frogs are highly specialized for growth and development in the aquatic environment (McDiarmid and Altig, 1999). They have an oval head-body region and a long tail, which is laterally compressed and includes a central area of musculature and dorsal and ventral fins of thin, lightly vascularized tissue. The tail is supported only by a notochord. Despite their very different body form, they swim and turn as rapidly and efficiently as fishes of similar body sizes. They have external gills, however, late in embryogenesis a fold of epithelium, the operculum, covers them, enclosing them and forming the opercular chamber. They filter feed using a mechanism that is very different from the oral morphology of adults. They pump water through the mouth and opercular chamber, where food particles are removed by branchial filters and entrapment in strands of mucus. Some tadpoles can remove particles as small as $0.126\ \mu\text{m}$ from the water. Water is ejected through the nostrils of most species and through the spiracle, which is usually a single, tubular structure leading out of the opercular chamber that can be located midventrally or on the left side of the body. The unique mouthparts of tadpoles typically include an oral disc with transverse rows of keratinized teeth that are used to scrape particles into suspension. Keratinized sheaths on the jaws serve as cutting and biting surfaces. The oral apparatus is variously modified and sometimes allows attachment to the substrate via suction (Figure 1(d)). The relatively long, coiled intestine fills most of the body cavity. Tadpoles are typically thought of as microphagous herbivores that feed on algae and small parts of higher plants, but most species will feed on animal material when it is available. Tadpoles often scavenge on dead animals in the water and frequently prey on amphibian eggs. They typically feed at high rates, retain food in their guts for relatively short periods, and extract only a small fraction of the energy from ingested food. This makes them an important source of the fine particulate organic matter that many aquatic invertebrates depend on for food.

Tadpoles often hatch before the opercular chamber forms, and many species initially do not swim but attach to a substrate using adhesive organs located posterior to the mouth. Swimming usually commences with the closing of the operculum. Tadpoles lack limbs at hatching. The rear legs usually develop slowly, starting as limb buds at the posterior end of

the body and developing over a long period. The forelimbs develop within the opercular chamber and are visible only after they erupt fully formed through the opercular wall at the onset of metamorphosis.

A typical pattern of tadpole growth and development would include one to a few days as a nonswimming hatchling with exposed gills followed by several weeks to months as a swimming and feeding larva. During this period, the tadpole grows dramatically; many species increase their body mass by hundreds of times and some by thousands. During this period, the hindlimbs begin to grow and slowly develop through the remainder of larval life.

Metamorphosis begins with the eruption of the forelimbs and involves drastic changes to all elements of the structure and function of the body. Reorganization of the mouth and digestive tract allows a switch from larval filter feeding to adult carnivory. The tail fins and musculature are broken down and reabsorbed. Most elements of the chondrocranium are reshaped and realigned, and the branchial apparatus ceases to be a support for gills and takes on a role as support for the adult tongue. The external and middle ears form, and in all but a few aquatic species the lateral line system disappears. The eye changes in size and structure, the photopigments of the rods change from porphyropsin to rhodopsin, and eyelids appear. The axial skeleton is reorganized and many elements are ossified. The lungs, which begin to develop and function during the larval period of many species, enlarge and take on their role as a major respiratory structure. The complexity of the skin increases, with the epidermis increasing from two layers of cells to five or six, many with specialized functions. The kidney, which in tadpoles is relatively simple and excretes excess water and ammonia, becomes more complex to serve its new function of conserving water and excreting urea. The gonads differentiate at about the time of metamorphosis.

Rates of growth and development of tadpoles are typically highly variable within species, responding to environmental temperature, food availability, and the density of tadpoles of their own and other species. Many species that inhabit unpredictable environments, such as temporary ponds, can have larval periods from 2 weeks or less up to months. Some species regularly spend 1 year or more (maximum 3 years) as larvae. The interaction between rates of growth and development in tadpoles has produced a rich literature that examines how and why this interaction is controlled. In general, it appears that rates of growth control rates of development during the earlier part of the free-living tadpole stage (Wilbur and Collins, 1973). Larvae that are growing slowly develop more slowly than fast growers, and changes in growth rate caused by changes in environmental conditions are mirrored by alterations in developmental rate. Fast-growing tadpoles tend to metamorphose both earlier and at larger sizes than slower growing individuals. Very slow growers appear to regulate their developmental rate so that they metamorphose near a species-specific minimum size after a larval period that may vary greatly in length. This flexibility in relative rates of growth and development is lost late in the larval period at a point that may vary among taxa. Theory suggests that the regulation of these rates ultimately responds to natural selection acting in a way that depends on the relative rates of growth and survival in aquatic and terrestrial environments. These ideas have been

applied to life-history transitions in many other taxa, including fishes, insects, and plants.

Because frogs typically deposit large numbers of eggs during relatively short breeding seasons, densities of tadpoles are often high. The success or failure of a cohort of tadpoles in a typical temporary freshwater habitat depends on a highly complex and unpredictable set of factors, including the density of tadpoles of their own species and other species, which control the degree of intraspecific and interspecific competition for food and space; the number and species of predators present; and the duration of the aquatic phase of the habitat. Competition and predation are both controlled by the choice of time and place of breeding by adult frogs and to some extent by microhabitat selection within habitats by tadpoles. The outcomes of species interactions involving tadpoles can be altered by changes in the timing of breeding, and microhabitat selection by tadpoles can depend on the species and sizes of other tadpoles present.

Tadpoles are preyed on by a wide variety of vertebrate and invertebrate predators, for whom they constitute a valuable resource. Major predators include fishes, salamanders and salamander larvae, and the aquatic larvae of insects such as dragonflies, damselflies, and beetles. Some species alter their color patterns or tail morphology in response to the presence of certain predators. Vulnerability of tadpoles to predators typically decreases as the tadpoles grow and develop, and many tadpoles exhibit short-term behavioral responses to predators, such as decreasing their levels of activity or switching from midwater feeding to substrate feeding, that appear to decrease their vulnerability. Most of these responses also decrease the tadpoles' rates of growth and development, leading to trade-offs that have been explored by behavioral ecologists.

Behavior and Ecology of Postlarval Amphibians

The ecological breadths of the three classes of modern amphibians are reflected in their geographical distributions (Savage, 1973). The caecilians are restricted by both thermal and water requirements to relatively low latitudes and elevations, and they do not occur where mean annual temperatures are less than about 12 °C or total annual precipitation is less than about 1000–2000 mm. The salamanders have less restrictive ecological requirements and are distributed across a broader range of habitats, occurring from low to high latitudes and elevations. Their major limitation is clearly moisture; they do not occur in areas that have prolonged dry seasons and only rarely in areas with total rainfall less than 1000 mm per annum. The anurans as a group can tolerate wide ranges of both temperature and water availability, and they occur at all but the highest latitudes and elevations and in all but the driest deserts.

Almost all adult amphibians are relatively nonselective carnivores that ingest invertebrate and vertebrate prey small enough to be swallowed whole. Amphibians are either sit-and-wait predators or active foragers, but do not engage in cursorial pursuit of prey. Sit-and-wait predators locate their prey primarily using vision, whereas active foragers often use olfaction.

Salamanders use a variety of methods for prey capture. Many larvae, and adults of aquatic taxa, are suction feeders, using rapid depression of the floor of the mouth and throat to

pull in water and prey. Terrestrial salamanders usually feed by extending their large, fleshy tongues, which adhere to prey and pull it into their mouths. The tongue of salamanders is attached at the base and is protruded and elongated by muscles and fluid tension. The degree of attachment of the tongue and the length to which it is protruded vary among taxa. Captured prey are ingested whole. Terrestrial anurans also capture prey by protruding their tongues. These are usually attached near the front of the lower jaw and are protruded by literally flipping them forward and downward. Prey that adhere to the tongue are drawn into the mouth and swallowed whole.

Amphibians generally appear to grow throughout their lives, but rates of growth decline drastically after reproductive maturity is attained. In captivity, many species can live for decades, and even in nature some species live for extended periods. In general, amphibian life spans appear to be limited more by environmental hazards than by aging and senescence.

Many species of frogs and salamanders occupy relatively small home ranges during the nonbreeding season and migrate to breeding habitats for reproduction. The nonbreeding home range is aggressively defended by some species. Some species return to their natal ponds to breed, whereas others may simply migrate to a suitable body of water. In temperate regions, some species may also regularly migrate to overwintering sites. Amphibians use celestial navigation, light polarization, and the Earth's magnetic field for orientation during migrations. There is considerable movement among local populations in many species, particularly by anurans. Some of this movement is dispersal by juveniles, but some is due to longer range movements by terrestrial adults. At least one species of frog, *Bufo marinus*, can move great distances over relatively short periods. The range of the introduced Australian populations of this species has expanded by approximately 30 km per year for an extended period, and the animals that arrive first in new habitat are adults. Detailed studies of the local movements of adult *B. marinus* suggest that they are nomadic. Many mark-recapture studies of frogs have found high rates of disappearance of marked frogs and of the appearance of unmarked animals, suggesting that adults of many species may at least occasionally disperse to new areas.

The relatively high rates of migration between local populations found in many amphibian species suggest that groups of local populations often form metapopulations. It is important to recognize this because the dynamics of metapopulations are governed by different factors than those of local populations, and the conservation of metapopulations requires a different approach than the conservation of local populations.

Because amphibians typically produce relatively large numbers of relatively small eggs, their populations can increase rapidly in size when reproduction is successful. It is likely that populations of most amphibians normally fluctuate fairly widely over time (Alford and Richards, 1999). It may be common for local populations of many species to fluctuate to extinction, followed by relatively rapid recolonization by immigrants from adjacent local populations belonging to the same metapopulation. It is likely that for many species the persistence of most local populations has little bearing on whether the regional metapopulation will persist. However, there may be a few critical local populations that either serve as reliable sources of

colonists or serve as stepping stones for migration between more widely distributed local populations.

It has recently become recognized that in some, and possibly many, species, rates of movement among breeding sites are so high that what had initially been thought of as isolated populations, one at each breeding site, and subsequently as metapopulations, with some breeding sites acting as sources and some as sinks, are in fact single populations, with unified dynamics, and that the appearance and disappearance of species at breeding sites may reflect short-term changes in habitat selection, rather than colonization and extinction. Understanding the nature of populations of threatened species is a very important step in conserving them, and much more needs to be done before the population biology of most amphibians is well understood.

Amphibian Conservation

Human Uses of Amphibians

Amphibians have featured prominently in many human cultures through stories, song, and poetry. In urban areas they are frequently found coexisting successfully with humans in parks and garden ponds. By consuming large numbers of insects, they are important in controlling agricultural pests and reducing disease transmission. Frogs are an important source of protein in some subsistence cultures. In affluent countries, frogs are imported for consumption in gourmet restaurants. Hundreds of millions of frogs have been exported from Southeast Asia and the Indian subcontinent, resulting in increased insect pest populations. Frogs have also become model organisms in ecological, embryological, physiological, and genetic research.

Amphibian skin contains a wide variety of chemicals, including complex amines, alkaloids, and polypeptides, some of which have pharmacological properties. Many skin secretions are effective against amphibian bacterial and fungal infections. Secretions of the South American frog *Epipedobates tricolor* contains a constituent, epibatidine, that blocks pain 200 times more effectively than morphine. Poison dart frogs of the family Dendrobatidae harbor many exceptionally toxic skin compounds and one species, *Phylllobates terribilis*, contains sufficient toxin in a single frog to kill several adult humans. This toxin is smeared on darts used by the Choco Indians of western Colombia for hunting monkeys and other large game. There are connections between frog diets and the presence of skin toxins; some dendrobatid frogs with high toxin levels in the wild gradually lose their toxicity when held in captivity. Although indigenous cultures have recognized the toxic and medicinal properties of frog skin for centuries, their potential for development as medicines using scientific methods has only recently emerged as a significant field of research, which has already yielded many compounds that may be of great use in combating a variety of illnesses, including the HIV virus.

Amphibians as Components of Ecosystems

Amphibians form vital links in many food webs. They constitute the highest vertebrate biomass in some ecosystems and

occupy an intermediate position in many food chains. Aquatic larval amphibians are herbivorous to omnivorous (most Anura) or carnivorous (Caudata and Apoda) and are significant prey items for a wide variety of vertebrate and invertebrate predators. Larval anurans often reach extremely high densities and can have a significant impact on nutrient cycling within freshwater habitats. Because tadpoles feed on algae and other aquatic material, they play an important role in the transfer of plant energy to predators of tadpoles. They also facilitate the breakdown of plant and animal biomass into plant nutrients; the extra nutrients regenerated by tadpoles can increase rates of primary production in freshwater systems, providing food at a higher rate to the tadpoles themselves. Adult amphibians feed on a wide variety of live food. Most are generalists that consume any living creature smaller than their gape size. However, some have specialized to feed exclusively on narrow ranges of food items, such as worms, ants, and even snails. Their effects on populations of their prey are probably important in many natural communities. Predators of amphibian eggs, tadpoles, and adults include other amphibians, spiders, insects, mammals, birds, and reptiles (especially snakes). Because of their important roles in ecosystems, population declines or extinctions of amphibians may have significant impacts beyond the amphibian species affected.

Amphibian Diversity and Threats to It

There are almost 7000 recognized amphibian species (Table 1), and many new species are being discovered and described every year. It has been estimated that the eventual number of species will be between 8000 and 10,000. Amphibians occupy all continents except Antarctica, and they are found in habitats ranging from arid deserts and saline mangrove swamps to tropical rain forests and mountain peaks more than 4000 m high. More than 80% of amphibians are found in the tropics, with an estimated 44% of the world's amphibians in the tropical Americas. Many tropical regions, including New Guinea, Southeast Asia, and parts of South America, have been inadequately surveyed, and there is no doubt that many new species will be discovered in these areas.

The conservation status of amphibians has deteriorated rapidly in recent years. The 1996 International Union for the Conservation of Nature (IUCN) *Red Data Book* listed five amphibian species as extinct and 124 as threatened, which represented 25% of the species for which assessment of conservation status had been undertaken at that time. Concern over the status of amphibians led the IUCN to conduct the Global Amphibian Assessment (GAA; Stuart *et al.*, 2004), which enlisted the aid of scientists throughout the world in determining the status of amphibians in their country or region. The results of this are frightening. In 2004, 1856 species, 32% of all known amphibians, were listed as threatened by the IUCN, with 427 listed as critically endangered. Thirty-four species were identified as being extinct, with nine having become extinct since 1980, and 122 as being possibly extinct, with 113 possible extinctions since 1980. In all, the GAA estimated that the conservation status of 435 species had become worse since 1980. All of these are probably

underestimates; although the GAA used the knowledge of more than 500 amphibian specialists, insufficient information was available on 1294 species (22.5%) to determine their conservation status, and many of the thousands of undescribed species that probably exist may also be under threat.

The Problem of Amphibian Population Declines

All amphibian populations fluctuate, and assessing the significance of downward trends in amphibian populations has been difficult. However, well-documented declines and disappearances of amphibian species and entire suites of species occurred over wide areas in the 1980s and 1990s, and continued in some places in the 2000s. These widespread losses of species and populations in a relatively short time frame, including dramatic extinctions of previously abundant species in protected areas such as national parks, are evidence that amphibians are experiencing a severe crisis.

Many causes have been postulated for amphibian declines, including habitat loss and modification, predation, environmental toxicity, disease, immunosuppression, ultraviolet radiation, changes in climate or weather patterns, and combinations of these. It is likely that many of these have caused some of the declines that have occurred (Alford and Richards, 1999; Alford, 2010). The GAA identified three major likely causes of declines in the 435 species whose conservation status had worsened since 1980. Overexploitation by humans appeared to be affecting 12% of these species, habitat loss 42%, and “enigmatic decline,” which was defined as declines occurring where there is suitable habitat and no other identifiable cause, was suggested as affecting the remaining 46%. Many of the enigmatic declines have involved rapid crashes of populations in relatively pristine habitats, such as montane rain forests. Lips *et al.* (2006) monitored a species-rich community in Panama before and during such a crash, and determined that it was caused by an outbreak of chytridiomycosis, caused by the amphibian chytrid skin fungus, *Batrachochytrium dendrobatidis*. This recently discovered disease is the proximate cause of many enigmatic amphibian declines. It infects the outer layer of amphibian skin via motile zoospores, which can be transmitted through contact or shared water. The host–pathogen ecology of this disease is complex; its prevalence and virulence are strongly affected by environmental temperature and humidity, and the timing of outbreaks of chytridiomycosis is probably affected by weather, and perhaps by changes in weather patterns related to global climate change. It is a very unusual disease in that it infects a very wide range of host species and can drive many of them to extinction, because resistant alternative hosts are common and it may also persist in the environment, independent of amphibian hosts.

In every area where there have been outbreaks of chytridiomycosis, some species have been driven to local extinction or very low numbers whereas others have persisted with endemic infections of the pathogen. The resistance of species to the development of disease is likely to be controlled by many factors, including the behavior and microhabitat selection of hosts, host population density, the types and quantities of antimicrobial skin peptides secreted by hosts, and the composition of the natural assemblage of microbiota

inhabiting the skin, some of which can compete with and inhibit the growth of *B. dendrobatidis*. In some places, including tropical Australia and some locations in Central America, some species have reappeared at some sites after initially disappearing. Research is underway to determine whether these reappearances result from increased disease resistance in amphibians, decreased virulence of the pathogen, effects of short-term variation in weather patterns, combinations of these, or alternative mechanisms.

It is likely that the pathogen has recently increased its geographic range, and it may even have spread globally from a single place of origin, possibly aided by human activities such as the extensive trade in amphibians for food, medical and scientific purposes, and as pets. Although genetic studies favor the hypothesis of a relatively recent spread and origin for most strains of the pathogen, the evidence is not conclusive. For example, in the California Sierras, there appears to be fine-scale genetic structure, suggesting that the pathogen may have been present for some time, despite the fact that declines linked to Bd have only recently been noted in the area (Morgan *et al.*, 2007). As more, and more thorough, surveys for its presence have been conducted, it has become clear that it is present in all continents occupied by amphibians, but appears to be absent from some areas, such as parts of far northern Australia, some parts of continental Asia, and the island of Madagascar. Some quarantine measures have been instituted, and more are needed. Knowledge of the status and distribution of the disease should increase since chytridiomycosis has been listed as a notifiable disease by the world organization for Animal Health (OIE).

At present, the only practical approaches to managing species that are severely threatened by chytridiomycosis are quarantine and the establishment of chytridiomycosis-free colonies of captive animals. Neither of these are likely to prove practical in the very long term, since the pathogen is clearly highly dispersive and captive management is expensive in resources and vulnerable to disruption. Approaches that have been proposed and are in various stages of development include probiotic manipulations of amphibian skin microbiota, artificial selection for increased resistance in captive populations, with resistant animals eventually reintroduced to the wild, and translocations of animals from populations that have developed naturally increased resistance.

A major hindrance to our understanding of amphibian population declines is a general lack of information about amphibian autecology and host–pathogen interactions, about how amphibian populations normally fluctuate, and about the extent to which they operate as metapopulations (Heyer *et al.*, 1994). In the short term, a great deal of research aimed at increasing our knowledge in these areas and testing hypotheses about population declines will be vital for identifying causal factors and determining how to eliminate or mitigate them.

Conclusion: The Amphibian Success Story and Its Future

Contrary to popular opinion, modern amphibians are not a relictual remnant of the ancestors of other tetrapods but are a highly successful group in their own right. There are more

species of amphibians than there are of mammals. Modern amphibians occur in nearly all of Earth's terrestrial habitats, from within the Arctic Circle to tropical deserts. Groups of modern amphibians that need to conserve water have evolved impermeable skins, cocoons, and the ability to excrete uric acid. Groups that need to breed outside water have evolved a startling array of reproductive adaptations; amphibians have the widest range of reproductive modes of any tetrapods. These include aquatic eggs and larvae, many species with terrestrial eggs, and truly viviparous species in which the mother provides nutrition in addition to the yolk during development. This diversity indicates that the typical reproductive pattern, with aquatic eggs and larvae, must not represent a constraint that has limited their success. It probably represents a successful adaptation that allows the exploitation of aquatic habitats by terrestrial species and allows a much higher fecundity than is available to species that must provision their eggs with enough yolk for complete development.

The ability to respond to environmental challenges has allowed the modern amphibians to persist and flourish during and through periods of dominance of terrestrial habitats by other tetrapod groups. They have outlived the early dominant amphibians, several waves of dominance by reptiles including the dinosaurs, and many radiations and extinctions of mammals. The current declines and disappearances of many amphibians may be an early manifestation of a general crisis in biodiversity, and unless they are halted it seems likely that future generations will be denied a full appreciation of the remarkable extent of amphibian diversity. It also seems likely, though, that as long as terrestrial habitats continue to accommodate vertebrate life, amphibians will persist.

Glossary

Biomass The total dry mass of a population or community of animals or plants.

Congener A species that belongs to the same genus as the one under discussion.

Elfin woodland Small, stunted tree growth characteristic of forests at higher elevations in warm, moist regions.

Endothermic An animal whose body temperature is largely determined by its own metabolism rather than by the temperature of the environment.

Epiphyte A plant that uses another plant, usually a tree, for support but not for nourishment.

Niche The unique position occupied by a particular species in terms of the function that it performs within the community.

Polyandrous A female that has more than one (male) mate.

Polygynous A male that has more than one (female) mate.

Trophic Relating to feeding.

Introduction

The life of birds is based on flight, which has both constrained their diversification and opened ecological opportunities. It affects their size and their abundance. Their ecology is based on the exploitation of patchy and variable resources, migration being the most obvious manifestation of this. A few birds are flightless. The taxonomic diversity of birds is limited. Across all continents, bird species diversity is greater in wooded than in forested habitats, generally being related to habitat complexity and productivity. Coexisting species eat different foods and often use different parts of the habitat. Bird species diversity is greater where there is greater habitat diversity; it is less at higher altitudes; and it is generally less as one moves from the tropics toward the poles, with strong local modifications. It may be correlated with that of other animals, but not always. Bird data have been used to test hypotheses about the causes of the latitudinal gradient in biodiversity. There is evidence that it is partly dependent on tropical regions providing more ecological opportunities, more habitable area, and more utilizable energy. No species is found all over the world. Some closely related species replace each other geographically. Some parts of the world, mainly tropical, have unusually large numbers of endemic, restricted-range species. Geological and evolutionary history has resulted in the avifaunas of different regions of the world differing in richness and taxonomic origin. Unrelated species living in different places but similar habitats have often undergone evolutionary convergence. Birds are good colonists of islands, where they subsequently evolve in the presence of few (if any) other land vertebrates. More species are found on larger islands, on those that once formed parts of larger landmasses, and on those closer to sources of colonists. Islands that become cut off from the mainland or which are fragmented lose species because extinctions are not then sufficiently matched by colonizations. Humans have caused the extinction of many birds, in both historical and prehistorical times, especially on islands. The chief current threats to them are habitat loss, hunting, agricultural intensification, and the introduction of alien species

to islands. Reducing these threats will be difficult. Avian biodiversity continues to be lost both by large-scale declines of many species in some parts of the world and by the introduction of species without their native ranges, which diminishes the differences in the bird communities of different lands.

Flight: Constraints and Opportunities

Birds as Flying Machines

The feather is one of the most remarkable structures ever to have evolved. It has allowed birds to become highly effective flying machines and to exploit resources in ways impossible for other vertebrates, although it has also placed constraints on them, considerably restricting their morphological diversification and thus limiting the ecological opportunities open to them.

Feathers provide highly effective insulation. Simply stated, the downy bases of the contour feathers trap a layer of air close to the body, and the integrity of this layer is preserved by the vanes of the feathers, which form a largely windproof and waterproof covering, like the tiles on a roof. Weight for weight, birds' plumage is considerably warmer and more waterproof than the hair and wool of mammals. Like mammals, therefore, birds are enabled to be endothermic, usually maintaining body temperatures well above their surroundings and thus leading active and independent lives.

The structure of feathers allows them to form strong but lightweight aerofoils, thus facilitating the evolution of wings. Since the wings are made up of many feathers, they are very adjustable, allowing effective and maneuverable flight. Because feathers have no blood supply, birds do not lose inordinate quantities of heat through their wings, as bats are in danger of doing. The bat wing is difficult to repair; in contrast, a damaged feather is renewed at the next molt. The strength of feathers allows birds to have long tails, which are used for both aerodynamics and social signaling, even though the

bony and fleshy tail on which those feathers are mounted is reduced to a short stub.

The shape of wings varies considerably. Long, pointed wings provide high speed but little maneuverability and lift; they are characteristic of birds that need to fly fast or migrate long distances and which live in open places, such as plovers *Pluvialis*. Short, rounded wings give maneuverability and lift but little speed; they are characteristic of woodland birds such as tits *Parus*. Large, broad wings allow birds to soar on rising air, covering long distances while patrolling the landscape for food; they are characteristic of large hawks, eagles, and vultures. Long, straight wings allow birds to glide on ocean winds; they are characteristic of albatrosses and other such seabirds.

Most vertebrates tend to have long, flexible bodies. Not so with birds: Flight requires a short, rigid trunk. This is achieved not only through the trunk being short and broad but also through the locking together of the skeletal elements, providing a firm base for the operation of the flight muscles while keeping skeletal weight down. Long bones are hollow, reducing weight. The compactness of the body is increased by having the major muscles of both wings and legs close to the center of mass, rendering locomotion mechanically efficient. Because the trunk is rigid, the neck must be long so that the head can be moved around. (The length of the neck is generally not apparent because of the covering of feathers.) Were birds to have a tidal airflow ventilating the lungs, this would be a major disadvantage, because in such a system there is a “dead space” lying between mouth and lungs into which air is drawn but never used. Birds have a through-flow so that all inspired air passes through the lungs. This is why they do not need to breathe as often as mammals of comparable size, even though they operate at the high metabolic rate that flight demands. Birds’ hearts are larger than those of similarly sized mammals to underpin their rapid metabolism.

The long neck means that it is particularly important for the head to be light. Modern birds are toothless and do not have the heavy jaws typical of many reptiles and mammals. Although their beaks and tongues are capable of remarkable feats of manipulation (such as finches husking seeds in seconds), this means that food is largely swallowed without chewing. To compensate, most species have part of the stomach modified as a muscular gizzard within which the food is ground. Indigestible elements of the food, such as bones, hair, arthropod exoskeletons, and husks, tend to be regurgitated in pellets.

As bats demonstrate, flight does not absolutely preclude viviparity; however, birds are the only vertebrate class in which no species bears live young. Weight restrictions result in most bats producing only one young per year, which prevents them from adopting “r-selected” lifestyles characterized by rapid reproductive rates. Some birds, in contrast, may produce well over 10 young each year. In those many species in which the young remain in the nest until fully grown, the parents’ ability to fly allows them nonetheless to forage over comparatively large areas.

Being so mobile in three dimensions, birds use vision and hearing as their dominant senses; they communicate mainly by sight and sound.

Size and Abundance

The constraints imposed by flight are nowhere as apparent as in the upper limit of bird size. The lifting power of wings depends on their surface area and on the cross-sectional area of the muscles powering them; however, the weight to be lifted depends on the volume of the body, so the ratio of weight to power increases with the size of the animal, imposing an upper limit on the size of flying animals. This appears to be approximately 15 kg for modern birds, exemplified by some swans, pelicans, and bustards, although some extinct species seem to have been appreciably larger. Flightless birds may be larger—more than 100 kg in the case of the ostrich *Struthio camelus* and approximately 450 kg in the extinct elephant bird *Aepyornis maximus*; however, even these are dwarfed by African elephants *Loxodonta africana* at 7 tons and blue whales *Balaenoptera musculus* at 100 tonnes. Flightless birds have no particular advantage over mammals and there are few of them.

Metabolic rate seems to impose similar lower limits on the size of birds and mammals: Kitti’s hog-nosed bat is 1.5–2.0 g, shrews such as the pygmy white-toothed shrew *Suncus etruscus* 2–3 g, and the bee hummingbird *Calypte helenae* 1.6–3.0 g. The problem is that metabolic rates of small endotherms are disproportionately great, partly because their large surface to volume ratio results in disproportionate heat loss. Not only is it difficult for them to ingest enough food to maintain such high rates but also there is an upper limit to the rates imposed by the rate at which their hearts can beat. The 1200–1400 contractions per minute observed in the smallest species may be the maximum achievable.

Most birds are small—half of the species weigh less than 38 g (Figure 1). They are larger toward the poles (Figure 2), perhaps because it is easier for large birds to keep warm or because they are more able to migrate long distances. Within the same region, smaller birds are more common in wooded than in open habitats; the former give them better protection from weather and predators as well as provide many foraging opportunities among twigs and foliage, which heavy birds cannot exploit. Waterbirds tend to be large to aid heat conservation.

In many birds, males are slightly larger than females; they are particularly large in many polygynous species, which suggests that the reason for the difference is the advantage that larger males have in competing for females. Females tend to be larger in polyandrous species and also in species in which males perform aerobatic displays as part of courtship.

On a logarithmic scale, the abundances of bird species in a region are approximately normally distributed, with some skew because of a tail of very scarce breeders (Figure 3). The same is probably true on a world scale. The Seychelles warbler *Acrocephalus sechellensis* was once confined to Cousin Island (29 ha), its population reaching a low of 50 pairs. Numerous other species confined to small, remote islands may have maintained populations of no more than a few hundred throughout their history. Various species have total world populations much less than this but usually as a result of human interference. Wilson’s petrel *Oceanites oceanicus* is probably the most common seabird, at 100 million or more. On land, the red-billed dioch *Quelea quelea*, of which individual flocks may number over 1 million, is almost certainly even more numerous; house sparrow *Passer domesticus* and starling *Sturnus vulgaris* are so

Figure 1 The frequency distribution of the logarithm of body mass of the 6209 species of birds for which data are available (reproduced from Blackburn TM and Gaston KJ (1994) The distribution of body sizes of the world's bird species. *Oikos* 70: 127–130).

Figure 2 The relationship in New World birds between body mass (geometric mean) and latitude (negative values are in the Northern Hemisphere) (reproduced from Blackburn TM and Gaston KJ (1996a) Spatial patterns in the body sizes of bird species in the new world. *Oikos* 77: 436–446).

widespread, partly through human introduction, that they may have total populations even greater than those of *Q. quelea*, which is confined to the more arid parts of sub-Saharan Africa.

At both local and regional scales, smaller birds are more abundant than larger ones (Figure 4). Species that are more abundant in places where they occur occupy more sites within regions (Figure 5) and have more extensive geographical ranges (Figure 6), though on both scales colonial species (which occupy few sites but at high densities) weaken the relationship. The correlation tends to be weaker outside the breeding season, perhaps because many noncolonial species then form flocks. Various reasons for this relationship have been suggested, but the evidence favors none in particular.

In Britain at least, summer visitors tend to be smaller, on average, than residents, perhaps reflecting difficulties that small birds have in keeping warm in winter. They are substantially less abundant than residents of the same size (Figure 4). (In North America, summer visitors are more abundant than residents; this is also true in Europe if one does not consider size.)

Figure 3 The frequency distribution of the population sizes of the 157 nonmarine native birds regularly breeding in Britain (British Trust for Ornithology data).

Figure 4 Relationships between abundance and body mass in non-flying mammals ($\circ$), bats (crosses), and resident ($\square$) and migrant ($\bullet$) nonmarine birds breeding in Great Britain. Note that both scales are logarithmic so that the mean difference in abundance between birds and nonflying mammals of similar size is approximately 45-fold (redrawn from Greenwood JJD, Gregory RD, Harris S, Morris PA, and Yalden DW (1996) Relations between abundance, body size and species number in British birds and mammals. *Philos. Trans. R. Soc. London B* 351: 265–278).

The Ecological Diversity of Birds

A 1-kg mammal can travel at sustained speeds of 6 km/hr, expending 118 kJ/km in doing so. A bird of the same size can travel at 47 km/hr, expending only 49 kJ/km. The power of flight thus allows birds to cover larger areas in the courses of their lives and this is the key to their ecology: They tend to use scattered and variable resources much more than

Figure 5 The relationship between the abundance of British upland birds in the sites at which they do occur and their frequency of occurrence at sites (reproduced from Fuller RJ (1982) *Bird Habitats in Britain*. Calton, UK: Poyser).

Figure 6 The relationship of mean local abundance and range size in European nonmarine breeding birds. The crosses mark species of special conservation concern (reproduced from Gregory RD, Greenwood JJD, and Hagemeijer EJM (1999) *The EBCC atlas of European breeding birds: A contribution to science and conservation*. *Biol. Conserv. Fauna* 102: 38–49).

do earth-bound animals. As a result, they are able to occupy significantly narrower ecological niches, subdividing resources more finely. This may be the reason why, within the same geographical area, the abundance of individual species of nonflying mammals is very much greater than that of birds of the same size (Figure 4). This, plus the fact that the average mammal is several times larger than the average bird, means that birds make up much less of the total biomass of terrestrial animals than do mammals (e.g., 13,000 tons for British resident birds versus 158,000 tons for mammals).

In contrast to such local restrictions on numbers, birds are able to occupy large geographical ranges because their powers of flight allow them to discover areas that provide them with the resources they require. Thus, local areas tend to be occupied by a higher percentage of the whole continental species pool of birds than is the case for other well-studied groups, such as mammals, amphibians, lizards, and butterflies.

Many waterbirds make seasonal use of water bodies that are impermanent or which freeze over in winter. On a shorter timescale, some species of birds (but few nonflying animals) move onto seashores in large numbers as tides recede, exploiting resources that are often rich but which are only briefly available. Pelagic seabirds use the efficiency of flight in another way, covering large areas in search of food that may be constantly available but is sparsely distributed. Outside the breeding season, they may move over thousands of kilometers, often along definite tracks determined by winds, currents, and seasonal availability of food. Seabirds quickly discover shoals of fish that are close to the surface, such as at upwelling fronts of cold water, which shift unpredictably. Even those land birds that are resident in a small area are constantly moving about that area in ways that allow them to subsist on food that is either sparsely distributed (such as seeds in temperate grasslands in winter) or which occurs in patches, especially temporary patches (such as carcasses, fruiting trees, nectar-bearing flowers, ant and termite swarms, insects disturbed by ungulate herbivores, and small animals disturbed by fire). Outside the breeding season they may temporarily use habitat patches that are inadequate to support them while breeding.

Birds are able to exploit aquatic habitats not just because of their powers of flight but also because of the effectiveness of their plumage for insulation. This is particularly important for smaller animals (because of their high surface to volume ratio)

Table 1 Numbers of bird families feeding on different food categories^a

Food category	Primarily	Regularly	Sparingly	Infrequently, if at all
Green plants, buds	2	13	13	140
Seeds	4	31	24	109
Fruit	19	34	21	94
Nectar	3	5	7	152
Insects	50	58	32	28
Other terrestrial invertebrates	2	10	23	133
Littoral and benthic invertebrates	6	10	13	139
Small vertebrates (<5 kg)	4	14	29	121
Large vertebrates (5 kg +)	0	0	3	165
Fish, crustaceans, squid, etc.	20	10	11	127
Carrion	1	4	6	157

^aReproduced from Morse DH (1975) Ecological aspects of adaptive radiation in birds. *Biol. Rev. Cambridge Philos. Soc.* 50: 167–214.

and it is noteworthy that there are few aquatic mammals weighing less than several kilograms. Those that do must frequently leave the water to dry out their fur. Insulation is less important for larger animals, and terrestrial mammals have given rise to cetaceans, sirenians, and seals, apparently excluding birds from occupying these ecological zones.

The Australian central desert, lying between two rainfall belts, may experience occasional rain at any time, anywhere; approximately 30% of Australian birds are essentially nomadic, settling to breed quickly in places where rain has fallen. Although some desert birds can survive without drinking much free water, others cannot; rather, they are able to live in deserts by using their powers of flight to reach isolated drinking places. Sandgrouse (*Pteroclididae*) may make round-trips of over 100 km daily between their nest sites and water holes, with males transporting water back to the chicks that is soaked into the modified breast feathers.

Although flight allows birds to exploit patchy resources, it also restricts what they feed on. To keep weight down, birds have short guts, through which food passes quickly; therefore, they tend to feed on particularly nutrient-rich items, generally eschewing food that needs to be taken in bulk. Insects (and other terrestrial invertebrates when available), littoral invertebrates, fruit, seeds, fish, and other small vertebrates are taken by many species but, despite leaves making up such a large proportion of the biomass on land, comparatively few birds are specialist leaf eaters (Table 1). Some grouse, geese and some ducks, some pigeons, the New Zealand ground parrot *Strigops habroptilus*, and the hoatzin *Opisthocomus hoazin* are exceptions: Most tend to feed selectively on the most nutritious leaves and to move their food through the gut rapidly.

Carrion is very sparsely distributed; therefore, only a few birds specialize on it, although there has been convergent evolution on this specialism in New and Old World vultures. Similarly, nectar is only found in sufficient quantities for birds to use in some parts of the world and efficient nectar-feeding

Figure 7 Examples of beaks used for various ways of feeding: 1, flamingo, modified for filter feeding; 2, toucan, elongate for reaching suspended fruit and secondarily decorated for social signaling; 3, merganser, serrated for gripping fish; 4, woodpecker, chisel-shaped for probing wood; 5, crossbill, specialized for extracting seeds from cones; 6, hummingbird, elongate for reaching nectar; 7, warbler, fine for picking up insects; 8, puffin, deepened for carrying several fish at once and secondarily decorated for social signaling; 9, shrike, hooked for tearing prey; 10, swift, wide for catching insects in flight (illustration by Su Gough).

requires anatomical and behavioral specializations so there are few families for which nectar is the primary food (and, as with the vultures, there has been a convergence of New and Old World forms: humming birds and sunbirds, respectively).

The various diets of birds are associated with a variety of bill shapes (Figure 7). There are subtler variations: Frugivores with wider gapes take larger fruits, and finches with deeper bills take larger and harder seeds. Even within species, differences between individuals in bill size may be reflected in diet, the most extreme example being the African finch *Pyrenestes ostrinus* in which there are two genetically distinct forms specializing on sedge seeds that differ in hardness. The extinct

Huia *Heteralocha acutirostris* of New Zealand fed on insects in dead wood, with the female probing into borings with her long, pliant bill and the male chiseling the wood open with his shorter, stouter bill.

Migration

The most dramatic manifestation of birds' use of varying resources is migration. Huge areas of North America, Europe, and Asia become inhospitable to life in the winter, primarily because temperatures are low, the ground is snow covered, and waters are frozen; endothermic animals that could perhaps survive the physical conditions are often unable to survive in these regions because their food supplies are inadequate. Therefore, there are relatively few permanently resident birds. In the summer, however, there is an abundance of food and this presents an opportunity that is taken by hundreds of millions of birds from south temperate, subtropical, and tropical regions that move north to breed. Approximately 87% of the species breeding at 80° N in eastern North America are summer migrants, the proportion declining to 12% at 25° N. The same north-south pattern is seen in Europe but the proportion is consistently about 17% lower at equivalent latitudes because the warmer winters of western Europe allow more species to be year-round residents than in eastern America.

Not all movements are north-south. The comparatively warm (and damp) winter conditions on the western edge of Europe allow many waterfowl and shore-birds to winter there (such that British wetland sites tend to be more species rich in winter than in summer); these birds not only move north in summer but also move east, into continental regions where winter condition are intolerable. Summer visitors are generally more common in eastern than western Europe. Other species show altitudinal migrations, moving up into mountains to breed during short seasons of relative plenty. Within the tropics, savanna birds often have migrations that track the seasonally moving rainfall belts.

The seasonal variations in bird communities in particular areas may be complex. In the more benign parts of temperate regions, for example, such as the southern United States and Mediterranean Europe, winter visitors from the north and summer visitors from the south effectively replace each other. Thus, 52% of the wintering species at 25° N in eastern North America are visitors that have bred in the north; the proportion declines further north, to zero at 70° N. A similar pattern is seen in Europe, but there are about 10% fewer northern migrants at equivalent latitudes.

Summer migrants to North America mostly come from Mexico, Central America, the Caribbean, and northern South America rather than beyond the equator. These places are, if not forested, well wooded. Pale-arctic migrants come from similar latitudes, with 35% wintering wholly north of the equator and only 3% wholly south of it. In contrast to America, African migrants come almost entirely from savannas; these are not only much more extensive than forests in tropical Africa but also much more seasonal.

In much of Europe, summer visitors seem to occur particularly in grasslands and scrublands. In British and Irish

Table 2 Percentages of birds (excluding seabirds) breeding in the western palearctic according to the way in which their range changes in winter^a

	%		
	Land	Freshwater	Coastal
Range is unchanged	44	25	8
North edge of range moves south (range contracts)	4	8	0
South edge of range moves south (so range expands)	4	5	0
Whole range moves south but summer and winter ranges overlap	18	46	46
Whole range moves south, summer and winter ranges do not overlap	30	16	46
Total number of species	399	63	26

^aReproduced from Newton I and Dale LC (1997) Effects of seasonal migration on the latitudinal distribution of west Palearctic bird species. *J. Biogeogr.* 24: 781–789.

woodlands, migrant passerines are most common in early successional stages and also in the upland oak-woods of Wales, where residents are less abundant than in lowland woods; migrant species are generally less abundant and less widespread than residents and use a less diverse array of nest sites. These patterns fit with residents, where they can survive the winter, preempting habitats, with migrants utilizing the summer surplus that the residents cannot fully take up.

There is much less land in the Southern Hemisphere than in the north. As a result, in both Africa and South America, although there is some migration between tropical and south temperate regions, it is less dramatic than the northern migration. As in the north, relatively few of the migrants cross the equator.

Although generalizations about migration can be made, there is much variation between species in details, as is apparent even from broad considerations of patterns of migration (Table 2). Most migration is within-tropical, within-temperate, or tropical-temperate but there are a few species, such as American golden plover *Pluvialis dominica*, that move between temperate zones in the two hemispheres. At the extreme, some arctic terns *Sterna paradisaea* breed in the Arctic but winter in the Antarctic.

There is variation even within species: Populations (and even individuals within populations) may differ in whether they are resident or migratory and, if migratory, how far they migrate and by what routes. "Leapfrog" migration is not uncommon. In the fox sparrow *Passerella iliaca*, for example, populations of Vancouver Island and the nearby mainland are resident; birds wintering in Oregon breed in the far southeast of Alaska and northern British Columbia; and those wintering in California breed further north and west, along the Alaskan peninsula.

Flightless Birds

A few bird species are flightless. Given that it is the demands of flight that are responsible for the restricted morphological diversity of birds, it is not surprising that some of these

flightless species show marked departures from the typical avian body plan.

Many species that have colonized remote oceanic islands have become flightless. Such islands hold few, if any, other terrestrial vertebrates so there is a variety of vacant ecological niches available for birds to exploit, including those based on resources that, being neither patchy nor unpredictable, do not demand the power of flight for their exploitation. Nor is flight needed as a means of escape in the absence of predators. Among the flightless species on remote islands, rails (Rallidae) feature prominently. Rails generally lead a sedentary existence, using their powers of flight mainly for long-distance migration and to find isolated habitat patches. Island rails have typically achieved flightlessness, as have some other species (ratites in particular), by neoteny, i.e., the retention of juvenile features into adulthood. The key retained features are that the keel on the sternum (on which the massive flight muscles are inserted in flying birds) is absent (or much reduced), the legs are comparatively large, and the plumage is often looser than in typical birds, because the barbs that make up the vane of the feather lack the barbules that, in typical feathers, link adjoining barbs together to make the vane a continuous plate.

Other highly modified island forms, now extinct, were the dodo (*Raphus cucullatus*) of Mauritius and the two species of solitaire (*Pezophaps*) on Rodriguez and Réunion. Turkey-sized birds descended from doves, these species are typically pictured as exceptionally ponderous, although it has been argued that they displayed a marked annual cycle of fattening and that for much of the year they were far slimmer than usually portrayed. They had massive legs and bills and apparently occupied the niche of generalist herbivores, taking large seeds and foliage.

Apart from bats, New Zealand remained mammal free from its time of isolation from Australia 75–80 million years ago until colonized by man about 1000 years ago. In its forested landscape, moa (Dinornithidae) evolved: These were moderate to large birds, somewhat ostrich-like but much more sturdily built, and they usually held their necks horizontal rather than upright; they roamed scrubland and forests in search of seeds, fruit, and shoots. There were about 11 species, all extinguished by man. Kiwis (*Apteryx*), however, survive in small numbers. They are behaviorally and anatomically highly modified for feeding on soil invertebrates, with the nostrils on the tip of the elongate bill (unique among known birds). They are nocturnal. Apart from their locomotion being bipedal, they look remarkably mammal-like when rooting along the forest floor or across pastures in search of food. Another remarkable New Zealand species is the kakapo (*Strigops habroptilus*), an herbivorous flightless parrot; although a few other parrots are largely terrestrial, this is the only flightless species.

The moa-like elephant birds (Aepyornithidae) of Madagascar also evolved in isolation, with their final extinction apparently coinciding with the arrival of man. What of the surviving large flightless birds—the ostrich (*Struthio camelus*) of Africa, the two rheas (Rheidae) of South America, the emu *Dromaius novaehollandia* of Australia, and the three cassowaries (*Casuaris*) of Australia, New Guinea, and nearby islands? It is possible that all except the ostrich evolved in the absence of predators, although they have encountered them since; ostriches and rheas, living on open plains, can run at great

speed. All have continued the bird habit of feeding on scattered food (fruit, seeds, flowers, shoots, and the more nutritious leaves, plus small animals in the case of emu and rheas), covering large foraging areas on their long legs and using the reach of their long necks to pick out food items.

The ecological gap left by the extinction of carnivorous bipedal dinosaurs led to the evolution of various giant flightless predatory birds but these seem to have been unable to survive competition from modern carnivorous mammals.

Waterbirds use two different techniques to swim under water, both of which result in a predisposition to the evolution of flightlessness. Some use their feet to drive themselves through the water. Thus, in addition to retaining the massive wing muscles required for flight, these birds must also have particularly powerful hindlimbs. More important, efficient movement through the water requires an elongate body, conflicting with the benefit for flight of a short, compact body. The powers of flight are therefore reduced in many foot-swimmers; species in isolated situations have become flightless, such as the Galapagos cormorant (*Nannopterum harrisi*) and the Lake Titicaca grebe (*Centropelma micropterus*).

The second underwater swimming technique is to use the wings, as do the auks (Alcidae) of northern seas. Since water is denser than air, the wing feathers need to be short if they are not to bend too much. Indeed, not only can the whole wing be much smaller but also it must be; otherwise, the wing muscles would not be strong enough to move it. It is not surprising that the Great Auk (*Alca impennis*) and other large species now extinct were flightless. In the Southern Hemisphere, even greater specialization for swimming occurred in the penguins (Spheniscidae). Their flippers are mostly made of muscle and bone, with the feathers on them being as short as those on the rest of the body. To prevent the bird from being too buoyant, the downy layer is not as well developed as one might expect for animals living in cold water; instead, penguins may carry much subcutaneous fat. Their bones tend to be solid. The elongation of their bodies is so great that they have to stand upright when on land. It can clearly be seen how giving up flight has liberated them from the constraints of body form that apply to most birds.

The Taxonomic Diversity of Birds

Approximately 9700 species of birds are currently recognized, which is more than twice as many as there are species of mammals. The great number of avian species is remarkable given the restrictions on morphological diversity imposed by flight, but it is undoubtedly a consequence of flight. As already considered, the mobility that flight provides allows birds to occupy finely divided niches. It also allows them to colonize isolated islands and habitat patches, where the original colonists may evolve into new species. (Note that bats, similarly equipped with the powers of flight, resemble birds in terms of their abundance/size relationships (Figure 4) and they are the second most species-rich order of mammals, with approximately 950 species).

Table 3 shows the orders of birds recognized in traditional classifications of birds and those determined on the basis of studies of DNA hybridization. Many of the differences are

Table 3 Traditionally recognized orders of birds and those based on DNA hybridization, with numbers of species in the latter^a

	<i>Traditional</i>	<i>Sibley and Ahlquist</i>	<i>Species</i>
Rheas	Rheiformes	Struthioniformes	10
Ostriches	Struthioniformes		
Cassowaries	Casuariiformes		
Kiwis and moa	Dinornithiformes		
Tinamous	Tinamiformes	Tinamiformes	47
Grouse, pheasants, guinea fowls, and quails	Galliformes	Galliformes	214
Guans and megapodes		Craciformes	69
Swan, geese, ducks, and screamers	Anseriformes	Anseriformes	161
Woodpeckers and barbets	Piciformes	Piciformes	355
Jacamars	Coraciiformes	Galbuliformes	51
Hornbills		Bucerotiformes	56
Rollers, motmots, knifishers, and bee-eaters		Coraciiformes	152
Hoopoes		Upupiformes	10
Trogon	Trogoniformes	Trogoniformes	39
Mousebirds	Coliiformes	Coliiformes	6
Cuckoos and hoatzin	Cuculiformes	Cuculiformes	143
Parrots	Psittaciformes	Psittaciformes	358
Swifts	Apodiformes	Apodiformes	103
Hummingbirds		Trochiliformes	319
Turacos and plantain-eaters	Musophagiformes	Musophagiformes	23
Owls	Strigiformes	Strigiformes	291
Nightjars and oilbird	Caprimulgiformes		
Doves and dodos	Columbiformes	Columbiformes	313
Sunbittern, bustards, cranes, Kagu, rails, etc.	Gruiformes	Gruiformes	196
Button-quails		Turniciformes	17
Sandgrouse	Pteroclidiformes	Ciconiiformes	1027
Shorebirds, gulls, terns, and auks	Charadriiformes	Passeriformes	5712
Grebes	Podicipediformes		
Cormorants, pelecans, gannets, etc.	Pelecaniiformes		
Hawks, eagles, falcons, secretary bird, etc.	Falconiformes		
Storks, herons, ibises, etc.	Ciconiiformes		
Petrels, shearwaters, and albatrosses	Procellariiformes		
Divers	Gaviiformes		
Penguins	Sphenisciformes		
Flamingos	Phoenicopteriformes		
Perching birds	Passeriformes

trivial: The four orders united into the Struthioniformes on the basis of the DNA evidence have always been recognized as closely related; the splits of several orders generally correspond with long-recognized subordinal divisions. The most fundamental difference is not just that 10 apparently diverse orders are united into the Ciconiiformes by the DNA evidence but also that some of these orders have not retained their integrity as major subdivisions within the combined order. Further work is needed before these changes can be accepted or rejected.

The classification based on DNA hybridization groups the orders of modern birds into two "infra-classes," Struthioniformes plus Tinamiformes (Eoaves) and all the others (Neoaves). This is a long-recognized division based on the peculiar structure of the palate and other anatomical characteristics of the first group. Eoaves are often referred to as ratites, although strictly speaking this term should not include the tinamous since it refers to the condition of the sternum in the struthioniform birds, which is flat, without the keel on which the flight muscles of most birds (including tinamous) originate.

Both the traditional and the DNA-based classifications recognize more orders of birds than the 21 usually recognized for mammals. Given that birds are substantially less diverse than mammals, this is paradoxical. It reflects the fact that taxonomic categories at the same formal level in the hierarchy are not comparable in different groups and that ornithologists have adopted classifications that specialists in other disciplines would regard as inflated. (Entomologists would probably reduce most ornithological families to the rank of genus.)

The outstanding feature of avian taxonomic diversity is that 59% of the species belong to one order, the Passeriformes. In contrast, the most species-rich order of mammals (the rodents) comprises only 42% of the species. The passerines are "typical birds." They are characterized by a particular form of the foot, well suited to perching, but have no obvious single characteristic that would appear to open up ecological opportunities in the way that the special gnawing incisors seem to have done for the rodents. Perhaps their numerical dominance is simply related to their small size, given that most birds are small (*see* Flight: Constraints and Opportunities – Size and Abundance). An additional peculiarity is that the two

Figure 8 The numbers of species in British bird communities, according to how many are found on more than 25% of sample sites for each habitat and how many on more than 75% (from data in Fuller RJ (1982) *Bird Habitats in Britain*. Calton, UK: Poyser).

suborders of passerines are disparate in size, with 80% of the species falling into the suborder Passeri (or oscines), the true songbirds, and only 20% in the suborder Tyranni (or suboscines). Speciation in songbirds often seems to involve the evolution of song differences between formally conspecific populations. Perhaps the complex vocal apparatus of oscines has promoted high rates of speciation, leading to this suborder (and thus the order to which it belongs) being remarkably species rich.

Another peculiarity of birds, particularly if one considers that avian orders are comparable to taxa of lower rank in other animal groups, is that only a few of the orders contain very few species. The Coliiformes is the only order with less than 10 species, whereas six mammalian orders have fewer than 10. The most taxonomically isolated bird species, generally given families of their own, include the secretary bird *Sagittarius serpentarius*, a large ground-living raptor of African savannas; the hoatzin *Opisthocomus hoazin*, a leaf-eating oddity related to cuckoos which inhabits permanently flooded forests in South America, with an enormous specialized crop for processing its unusual diet; the kagu *Rhynochetos jubatus*, a strange, short-legged flightless gruiform endemic to the forests of New Caledonia; and the oilbird *Steatornis caripensis*, a Neotropical caprimulgid that feeds on fruit by night using sonar to navigate around the dark caves into which it retreats by day. Despite their peculiarities, none of these is as divergent from the rest of their class as is the aardvark *Orycteropus cafer*, placed in an order all its own among the mammals.

Habitat and Bird Species Diversity

Differences between Habitats in Bird Species Diversity

It is a matter of common observation that habitats in the same region differ in the species diversity of the bird communities living in them. Habitats with higher diversity also tend to hold

larger numbers of individual birds. However, there have been few systematic surveys of bird communities across all the habitats in a region and even fewer with the extent of replication used for the data in **Figure 8**, in which each habitat was represented by at least 12 sites (with a mean of 72 sites/habitat). This confirms the following generalization: Woodlands, scrub, and carr contain large numbers of species, whereas open downland contains very few. Machair, flat plains based on deposits of calcareous sand fringing parts of the western seaboard of northern Scotland, is a conspicuous exception, having large numbers of birds despite being completely unwooded. This may be the result of the extreme small-scale heterogeneity of machair lands: There may be a transition from mobile sand dunes to stabilized grassland, from very dry to very wet conditions, and from undisturbed to cultivated ground within distances of tens of meters.

The distributions of the points on the two axes of **Figure 8** are correlated: Woodland tends to have many of the more ubiquitous species (occurring in more than 75% of the sites) and the less ubiquitous (occurring in only 25–75% of sites), whereas open downland holds few of either. The scatter around the correlation, however, reveals further differences between habitats. For example, scrub is an ephemeral habitat, typically occupied by species that are good colonists and which therefore tend to be found in the majority of sites; as a result, two-thirds of the species found in more than 25% of scrub sites are actually found in more than 75% of sites.

Bird Species Diversity in Similar Ecosystems on Different Continents

If habitat is a major determinant of bird species diversity, one would expect to find similar levels of diversity in similar vegetation and landscape types on different continents. Often one does, but sometimes one does not (**Table 4**). Even where total species numbers are similar, the numbers of species

within individual feeding categories may differ. Thus, although numbers of bird species in most feeding categories are similar in Mediterranean scrub in Provence (France), Chile, and California, Provence has no nectarivores and only 4 granivores, in contrast with 3 and 14, respectively, in

Table 4 Numbers of bird species in similar habitats on different continents^a

Habitat	No. of species	
Peatlands	33 (Finland)	18 (Minnesota)
Desert	57 (Arizona)	61 (Argentina)
Shrub desert	5.5 (Australia)	6.3 (N. America)
Mediterranean scrub	30 (California)	28 (S. Africa)

^aData collated by Schluter D and Ricklefs RE (1993) Convergence and the regional component of bird species diversity. In: Ricklefs RE and Schluter D (eds.) *Species Diversity in Ecological Communities*, pp. 230–240. Chicago: Univ. of Chicago Press.

California and 2 and 6 in Chile. Again, the species richness of semiarid habitats is similar in North America and Australia, but the bird communities are clearly different in detail, partly perhaps as a result of different evolutionary histories but partly because rainfall is more erratic in Australia than in North America. Thus, the habitats are similar but the overall environmental conditions differ significantly. Despite differences in species number, the number of species in the various feeding categories tends to depend more on habitat itself than on what continent the habitat is in (Table 5).

Bird Species Diversity and Habitat Complexity

Although it is not a universal rule, most studies have tended to confirm the discovery by R. H. and J. W. MacArthur that bird species diversity is positively correlated with foliage height diversity, at least in scrub and woodland habitats (Figure 9). That is, bird species diversity is greatest where there is an equal volume of foliage at all heights in the woodland. An early finding was that data points from Australia fell on the same line as those from the original study in North America. However, MacArthur discovered that data from Panamanian and Puerto Rican sites only fell on the same line if the measure of foliage height diversity was adjusted by changing the height subdivisions on which it was based. His interpretation was that Panamanian birds were effectively treating the forests as being divided into more layers than were North American birds, whereas Puerto Rican birds were treating them as being more coarsely divided. Similar variations have been found elsewhere and may be related to the productivity of the different areas. Where there are more resources available, species may divide them into narrower ecological niches; perhaps more simply, more resources allow more individual birds to live in an area and thus allow even relatively scarce species to maintain viable populations.

Along an altitudinal gradient from lowland rain forest at 400 m to elfin woodland at 3600 m in the Peruvian Andes, bird species diversity and foliage height diversity decline approximately in parallel. However, the magnitude of the decline

Figure 9 The relationship between songbird species diversity and foliage height diversity in Scottish woodlands. Some points are averages over 2 or 3 years. Both diversities are measured using the Shannon index, (redrawn from Moss D (1978) Diversity of woodland songbirds populations. *J. Anim. Ecol.* 47: 521–527).

differed according to the diets of the birds in question. It was more than fivefold for insectivores but only two- or threefold for frugivores, whereas the species diversity of nectarivores was similar at all altitudes. These differences may be explained in terms of the resources available to different groups: Whole groups of insects are absent at higher altitudes; less fruit is produced at higher altitudes but a higher proportion is available to the birds because there are fewer mammalian competitors than there are at lower altitudes; and because of the distribution of flowers on the vegetation, the availability of nectar only increases slightly with foliage height diversity and, although the annual production of nectar is greater at lower altitudes, it is highly seasonal and therefore can support no more birds than the less abundant but more constantly

Figure 10 The relationship between bird species diversity and the percentage of the basal area of the forest comprising standing dead wood in Swedish woodlands (reproduced from Nilsson SG (1979) Density and species richness of some forest bird communities in south Sweden. *Oikos* 33: 392–401).

available nectar of the high-altitude forests. Thus, foliage height diversity is a crude measure of the diversity of ecological niches available to birds but it may become less satisfactory when one considers individual trophic guilds.

Since foliage height diversity is only a rough measure of niche diversity, it is easy to find other features of the habitat that influence bird species diversity. Thus, a survey of various sites in the Americas showed that although there was a good correlation between bird species diversity and foliage height diversity, the percentage vegetation cover of the ground also influenced the number of bird species. In other words, the total volume of vegetation was important, not just how it was structured. In hardwood forests of New Hampshire, for example, tree species differ in their value to birds: Some hold more food than others and some are easier to search (e.g., yellow birch *Betula alaghe-niensis*, with small leaves and short petioles); white ash *Fraxinus americanus* has a distinct foliage structure that allows fewer foraging methods to be used than do other species. Furthermore, floristic diversity is important: Even a few conifers in a hardwood forest allow in birds that specialize on such trees. In south Swedish forests the amount of standing dead timber (which is largely determined by how the forest is managed) chiefly determines bird species richness (Figure 10), with the density of low trees and shrubs having only a slight effect.

The most extreme case of the influence of factors other than foliage height diversity on bird species diversity occurs in forests in Patagonia, in which the relationship between birds and foliage diversity appears to be reversed (Figure 11). The reason for this is that the forests are of two quite different types and the type with the greater foliage height diversity (*Nothofagus* forest) has relatively few birds because it comprises patches that are isolated from other such forests by 2000 km of steppes and forests; furthermore, these forests are at high elevations, with harsh climates. The abundance of bamboo, which appears to support few insects, in the understorey of some of the *Nothofagus* forests may also be important. Note that even these species-poor forests hold

Figure 11 The relationship between bird species diversity and foliage height diversity in three contrasting habitats in northern Patagonia (reproduced from Ralph CJ (1985) Habitat association patterns of forests and steppe birds of northern Patagonia, Argentina. *Condor* 87: 471–483).

more species of birds than grasslands in the same region (Figure 11), fitting the usual pattern.

Horizontal complexity is also important, with more varied places holding more bird species. Edges between habitats may be bird rich for this reason, although “edge effects” are variable both in nature and in cause. In Britain, woodland birds are generally more abundant and more diverse at edges, probably because foliage height diversity is greater there than deep in the woodlands, where the lower levels of the vegetation tend to be shaded out. On Finnish islands, bird species diversity is lower on the edges of woodlands than deeper within perhaps because of the importance of physical protection during the early nesting period, when most of the trees have not yet begun to leaf.

Foraging Niches and Habitat Structure

Classic studies of the foraging behavior of tits in broad-leaved woodlands in southern England were conducted by David Lack and colleagues. In summer, all species tend to feed largely on the glut of caterpillars in the canopy; in winters during which the mast of beech *Fagus sylvatica* is abundant, they descend to the ground to feed on it. However, during the average winter their feeding niches are distinct. The great tit *Parus major* feeds mainly on the ground on beech mast, other large seeds, and larger insects. The blue tit *Parus caeruleus*, only about half the weight of the great tit and thus much more agile, frequently hanging upside down to reach its food, feeds high up in the trees, searching for small insects among the twigs, buds, and leaves. The less common marsh tit *Parus palustris*, although no heavier than the blue tit, has a larger beak and feeds on middle-sized insects, which it gathers in the shrub layer or from the twigs and branches of trees, lower down than where the blue tit feeds. Similar studies of other birds in many parts of the world have given similar results: Related species coexisting in the same forests and using broadly similar foods tend to differ in respect of the parts of the trees in which they forage. However, foraging height is not the only factor. Thus, the coal tit *Parus ater* in English broad-leaved woodland tends to forage at approximately the same height as the marsh tit, but it is a smaller species with a finer bill and it feeds on tiny insects that it finds in crevices on the bark. In addition, it is scarce in broad-leaved woods because it is a conifer specialist; its numbers are significantly enhanced when conifers are present—another example of the importance of floristic diversity for bird species diversity.

It is such differences in foraging site and food taken that allow different species to coexist in the same habitat. Introduced birds on Hawaii provide an unplanned experimental demonstration of how differences allow coexistence: Some species persisted for more than 10 years but then became extinct; extinction was particularly likely for species that had morphologically similar relatives (presumably taking similar diets) living in the same forest. Foraging niches sometimes, but not always, shift in apparent response to the presence or absence of competitors: Willow tits in northern Finland avoid the foraging positions of great tits *P. major* and crested tits *Parus cristatus* when in mixed flocks, but if either of these is absent from a flock the willow tits use the vacated niche.

Figure 12 The relationship between bird species richness, foliage density, and height above ground within a Peruvian forest (reproduced from Terborgh J (1980) Vertical stratification of a neotropical forest bird community. *Acta XVII Congr. Int. Ornithol.* 2: 1005–1012).

Different strata in forests differ not just in which species occupy them but also in their overall species richness. In the example shown in Figure 12, the forest floor, relatively uniform and simple in structure, supports few species—as does the high canopy, which is also relatively simple in structure. The middle layers support many more species because they are more complex, presenting opportunities for foraging on leaves, branches, bark, dead wood, epiphytes, termite nests, and accumulations of dead leaves in tree forks and for sallying from branches to capture insects flying in the open spaces below the canopy. Underlying the overall pattern of species richness are marked differences between feeding classes (Table 6): Mast is found either high in the canopy or fallen to the forest floor, so

most feeders occur only in these layers; gleaners are also mostly found low down or high up, working over the continuous substrates of the forest floor or the canopy; and salliers tend to occupy middle levels, where the open structure allows them to see and pursue flying insects. The canopy is a much patchier habitat than the understory because the crowns of individual trees occupy large areas, whereas the understory is composed of much larger numbers of plants; thus, the canopy presents particular opportunities to adaptable generalists that can switch, for example, from feeding on fruit to feeding on insects depending on what is immediately available.

Bird Species Diversity and Succession

Where sheep grazing is light enough to allow it, scrub invades open hill land in Wales, eventually developing into mature sessile oak (*Quercus petraea*) woodland. This vegetational succession is accompanied by an almost monotonic increase in the numbers of both individual birds and bird species (Figure 13). Most of the change involves increased vertical structure, although the latest stages result from gaps developing in the woodland canopy, with small patches of open ground and scrub. As chalk downland in southern England is succeeded by ever-denser scrub, species numbers increase monotonically from 1 or 2 per study site to approximately 15 (Fuller, 1982). More generally in Britain, the scrub that develops on downland and heaths and the carr that develops on rich fens hold more species overall and more of these species are found on a high proportion of individual sites (Figure 8).

The increase in bird species diversity may slow in later stages of succession. In a subalpine northern American sere comprising meadow, aspen (*Populus tremuloides*), fir (*Abies lasiocarpa*), and spruce (*Picea engelmanni*), the number of bird species averaged over 3 years was 3, 17, 22, and 21, respectively. Indeed, although as yew *Taxus baccata* woodlands in southern England mature they gain species steadily (10 species at 60–80 years old and 20 species at 100–200 years), the succession from open scrub with small stands of trees to the young closed yew woodland is marked by a decline from 26 to 10 bird species. Polish deciduous forest stands developing after clear-cutting reach their maximum bird species diversity when 100–150 years old but do not do so monotonically: Following a peak at 15–20 years, diversity declines for the next 15–20 years. Local factors may be important in determining the relationship between bird species diversity and habitat gradients, such as the gradient from very low matorral (0.5 m high) to mature forest of holm oak (*Quercus ilex*): Whereas the number of bird species increases along the vegetation gradient in mainland France, it decreases in Corsica (Table 7) because Corsican forests are very restricted and the island simply lacks many forest species found on the mainland, where they occur in large blocks of continuous forest. An additional complication to the story of Mediterranean holm oak forests is that, although the number of bird species in an area is reduced by fire, the reduction is less than expected from the change in vegetation structure. Some characteristic forest birds persist in the open areas and matorral created by the fire either because individual birds simply occupy the same territories or because they spill over from populations in nearby unburned forest.

Figure 13 The relationship between the number of breeding bird species and the total population density in sessile oak woods in Wales in various stages in the succession: 1, open ground; 2, low scrub; 3, medium scrub; 4, high scrub; 5, mature woodland; 6, mature woodland with gaps and scrub (reproduced from Jones PH (1972) Succession in breeding bird populations of sample Welsh oak woods, *Br. Birds* 65: 291–299).

Human management can produce habitats in which the normal pattern is disrupted. For example, when English woodlands are coppiced (the trees are cut to the ground but allowed to regenerate from the stumps), the dense, bushy regrowth is colonized by numerous species, but many of these are lost as the coppice ages and the tall regrowth forms a dense canopy that shades out the majority of the lower layers, producing a uniform, structurally simple habitat.

Even where the relationship between bird species diversity and habitat follows the typical pattern, this may not be simply because structurally less complex habitats provide fewer niches. Thus, bird species richness in cleared areas in Cameroon is much less than that in the forest (Figure 14), but this may be largely because the sources of open-ground species are savannas and grasslands that lie well beyond the surrounding forest so that the cleared areas may not have been fully colonized. (Note that this case also illustrates that just as different trophic groups of birds differ in their response to vegetation structure so do different taxa of animals generally: Butterfly species richness is affected by forest clearance in much the same way as that of birds but leaf-litter ants are more species rich in partially cleared and second-growth forests.)

In contrast to the absolute level of species diversities, the turnover of species during succession has been little studied.

Figure 14 Species richness of (a) birds, (b) butterflies, and (c) leaf-litter ants along a gradient of increasing habitat modification in Cameroon. 1, Near-primary forest; 2, old secondary forest; 3, partial manual clearance, plus plantation; 4, partial mechanical clearance, plus young plantation; 5, complete clearance, with young plantation; 6, manually cleared farm fallow (redrawn from Lawton JH, Bignell DE, Bolton B, *et al.* (1998) Biodiversity inventories, indicator taxa and effects of habitat modification in tropical forest. *Nature* 391: 72–76).

In Polish oak-hornbeam forests, there is a rapid shift in the early stages from species characteristic of open ground to those characteristic of scrub, but the rate at which species drop out of or enter the community slows as the succession progresses. In Finnish coniferous forests, in contrast, turnover peaks not at the start of succession but at 5–25 years.

Bird Species Diversity and Productivity

Many of the habitat differences that seem to influence bird species diversity are probably associated with differences in total biological productivity. Even with habitats of uniform physical complexity, such as the lakes of a region, differences in productivity are associated with large differences in the numbers of both individual birds and species present.

Geographical Variation in Bird Species Diversity

The Relationship Between Bird Species Diversity and Habitat Diversity

Different habitats have different bird communities. The greatest differences within geographical regions are between marine and terrestrial habitats since life on land and at sea requires different specializations. On land, the greatest differences are between bird communities of wooded areas and those of open country, just as these broad habitat categories show marked differences in overall species richness. However, the differences go beyond species richness: Grasslands differ from woodlands not just in that most of the woodland species are absent but also in that they have their own grassland specialists. The suites of species occurring in different habitats may be similar in size (number of species) but quite different in composition. For example, the numbers of nonmarine species occurring in more than 25% of sites in three British coastal habitats are 18 in sand dunes, 15 on rocky coasts, and 12 on salt marshes, but only 4 species are common to all three habitats and 6 common to sand dunes and rocky shores, whereas there are 7, 10, and 2 unique to sand dunes, rocky shores, and salt marshes, respectively.

Related species often differ in the habitats they occupy. For example, in Britain great tits *P. major* live in both deciduous and open conifer woods, blue tits *P. caeruleus* and marsh tits

P. palustris only in deciduous woods, and coal tits *P. ater* almost only in conifer woods. In central Sweden, marsh tits again occupy deciduous woods and willow tits *P. montanus* live in conifers but on the nearby Åland Islands, from which marsh tits are absent, willow tits occupy both.

Given such differences, one would expect bird species diversity to be correlated with habitat diversity in an area. Although this is undoubtedly the case, it has rarely been documented. However, a study of the boreal birds occurring on isolated mountaintops and mountain chains in western North America showed that 91% of the variation in species number could be accounted for by differences in habitat diversity.

Bird Species Diversity and Altitude

The decline in bird species diversity with increasing altitude in the Peruvian Andes (*see* Habitat and Bird Species Diversity – Bird Species Diversity and Habitat Complexity) is typical not just of forested regions but also of open habitats and not just of the tropics but also of temperate and boreal regions. Everywhere, there are fewer species of birds at higher altitudes—unless the higher levels have escaped habitat destruction wrought by man in the lowlands or unless the contrast is between different habitats, such as lowland savanna and montane forest. One cause of such gradients is that the structural complexity and the floristic diversity of the habitat are reduced at higher altitudes. This is true of both forests and open habitats; indeed, forest gives way to open habitats at sufficiently high elevation.

The cooler, windier, and wetter conditions at high altitudes are no doubt responsible for the less luxuriant vegetation and probably also affect the birds directly so that only species capable of withstanding them can survive. Some mountains may also be so isolated from others that they resemble islands, lacking some species because they have never reached these mountains or because they have not recolonized following a chance extinction (*see* Diversity on Islands).

Bird Species Diversity and Latitude

As with so many other groups, there are more bird species in the tropics than toward the poles (Figure 15), although some groups do not conform to this generalization: Only 3 of the 17 species of penguins (Spheniscidae) breed within the

Figure 15 The relationship in the New World between the species richness of birds breeding in a square and the latitude of the square (redrawn from Blackburn TM and Gaston KJ (1996b) Spatial patterns in the species richness of birds in the New World. *Ecography* 19: 369–376).

tropics (where marine productivity is low) and sandpipers (Calidridinae) breed mainly in the boreal tundra and taiga (utilizing the summer flush of productivity, especially in wetter areas). The trend occurs in all habitats but may be steeper in forests than in savannas and prairies.

The broad trend is modified by local contingencies. In Argentina, the trend is steepest where forest gives way to savanna. In Africa, the reduction in species number as one moves away from the equator is steeper to the north than to the south, in accord with gradients of aridity and vegetation diversity. Northern Finnish peat bogs hold more breeding bird species (and individuals) than southern ones, probably because they have willows (*Salix*) and therefore are more heterogeneous than the willow-free southern bogs. In Sweden, breeding passerine species are scarcer in northern than in southern bogs but waders are more diverse, with the northern bogs having more food-rich pools. In heavily urbanized locations in Finland, there is no latitudinal gradient in species diversity in winter because the birds are wholly dependent on man for food in such places. Mountain regions tend to be species rich because of their topographical and habitat diversity. Coastal areas differ from inland areas in diversity of nonmarine birds for reasons that are not clear: In North America they are comparatively poor in terms of breeding species, but in parts of Europe they are richer than inland squares.

Even at the continental scale, there are usually major departures from simple north–south trends. The pattern of aridity (and associated vegetation) largely determines bird species diversity in both Australia and Africa. In North America (Figure 16), the east is richer in breeding bird species than the west, although the far west is richer than the Midwest, especially in the mountains and the southwestern desert; in the east, there is a midlatitude peak in richness. The latter is also seen in Europe. It is not simply a gross pattern that might be produced by differences in the proportion of richer and poorer habitats because it is observed within individual habitats.

Figure 16 The distribution of species richness of insectivorous birds breeding in the United States. The depth of shading represents richness, from less than 70 species (pale) to more than 100 (dark) (redrawn from Schall JJ and Pianka ER (1978) Geographical trends in numbers of species. *Science* 201: 679–686, © 1978 American Association for the Advancement of Science).

Migration has major impacts on bird species diversity in many regions and habitats: It is substantially lower in the Arctic and much of the north temperate zone in winter than in summer and must vary considerably in African savannas because of migration both between Africa and the Palearctic and within Africa. This can modify geographical patterns of species richness. Thus, the difference between African forest and savanna is diminished, although by no means eliminated, in the northern winter because almost all the migrants move into the savanna; however, within the savanna the geographical pattern is maintained because areas rich in resident species are also areas to which most migrants move. In both Europe and eastern North America, the midlatitude peak of species richness in summer is eliminated in winter, when there is a simple north–south gradient.

Comparisons with Other Animals

There have been few direct comparisons between the geographical patterns of species richness of birds and those of other animals. In North America, a midlatitude peak in richness is also seen in mammals and amphibians, although the peak is further south, especially for amphibians. Reptiles show a simple north–south gradient. The decline in species richness in the north is steeper in mammals than in breeding birds, even steeper in amphibians, and steepest in reptiles. (Note, however, that many birds move out of the north in winter.)

Over North America as a whole, the species richnesses of birds and mammals are positively correlated but birds are not correlated with lizards and are negatively correlated with turtles and snakes. In Australia, there is a similar divergence: Birds are positively correlated with marsupials but negatively with lizards (which are species rich in hot, dry conditions, in which only specialist birds live).

Thus, although birds resemble other animals in showing a general tropical–polar gradient in species richness, local factors may affect them differently.

Causes of the Latitudinal Gradients in Species Diversity

Avian data have been widely used to illuminate possible causes of the tropical–polar gradient in species diversity. It is possible that it depends in part on there being more niches available in the tropics. Tropical vegetation is floristically more diverse and, in forests at least, structurally more complex. In North America, the midlatitude peak in bird species diversity is approximately matched by tree species diversity, as are the broad east–west trends. However, the relationship between the species diversity of birds and that of trees in North America is asymptotic; above a certain level, the richness of tree species appears not to influence that of birds. In Amazonian forests, 15% of bird species depend on habitats arising through dramatic fluctuations in river levels which do not occur in temperate regions. Furthermore, 34% of Amazonian birds belong to foraging guilds that are not found in temperate regions, such as obligate dead-leaf gleaners, obligate ant followers, and year-round frugivores; the rain forest's richness and comparative constancy provide opportunities lacking in temperate forests. However, this is not the whole story because even where guilds are found in both Amazonian and temperate forests they contain fewer species in the latter.

The North American midlatitude peak in breeding bird species diversity has been interpreted in terms of migration. At low latitudes, there are many year-round residents but at midlatitudes there are fewer; therefore, the summer provides many opportunities for migrants to pour in and to exploit the seasonal abundance of productivity. There is indeed evidence that insect food, although seasonally much more restricted in midlatitudes than in the south, is much more abundant when it does occur. Furthermore, it is migrants that feed on the insects that are active in summer that contribute most to the midlatitude peak; resident species such as woodpeckers, which have less seasonally variable food supplies, are not more numerous in midlatitudes than in the south. The hypothesis explains the decline in species richness in the far north (where there is also a summer flush of resources) in terms of constraints imposed by the shortness of the summer and the long journeys that migrants need to make to get there.

Another possibility is that the tropics are species rich because they include greater land areas, allowing more opportunities for speciation and reducing the likelihood of extinction. Although there is no correlation between the species richness of New World birds and land area at a given latitude outside the tropics, there is such a correlation if one excludes those species that are primarily tropical. It appears, therefore, that there is an underlying relationship between species richness and land area in the New World but that the very high richness of the tropics superimposes a wider gradient because some tropical species extend into subtropical and temperate regions.

An alternative hypothesis is that species richness is correlated with available energy in an area, either directly (warmer places allow animals to function more effectively) or indirectly, via productivity (higher productivity supports more individuals and therefore more species). Avian species richness in North America is correlated with potential evapotranspiration, which is a measure of available energy, but less well with actual evapotranspiration, which is more a measure of primary productivity. This supports the direct energy

hypothesis. In Britain, temperature gradients are north–south in summer but, because of the influence of the North Atlantic Drift, east–west in winter. Data on the distributions of resident and wintering birds have been used to test the species energy hypothesis, predicting different patterns of species richness in summer and in winter. Early analyses provided support for the direct effect of energy, including indications that correlations with temperature were greater for smaller birds (which are more susceptible to low temperatures). Recent work has not confirmed this result. Nor has it found seasonal changes in distribution that match the predictions of the direct energy hypothesis. Summer temperature is the best predictor (of various climatic and topographical variables) of bird species diversity in Britain, in both summer and winter. This suggests that birds in winter depend largely on productivity stored from the summer (in the form of seeds, nuts, and invertebrates).

Species Replacements Throughout the World

The Ranges of Birds

The barn owl *Tyto alba* is found in every continent of the world except Antarctica, and it is widespread in most of them. Most birds are much more restricted in terms of habitats, climate zones, and continents. Some occur on single small islands or isolated mountaintops. Differences in which species occur in which places are just as much a part of biodiversity as is the species diversity of individual places.

Species Replacements

Two species may have different geographical ranges because they live in different habitats that are found in different parts of the world. Alternatively, they may occupy similar habitats but simply have evolved in different places. Thirdly, they may originate in isolation from each other, subsequently come together, but be ecologically so similar that competition prevents them from coexisting, except perhaps in limited areas (Figure 17). If they differ sufficiently in feeding habits or habitat, coexistence is possible but the extent of this varies between different sorts of birds, between breeding and winter quarters, and (within a taxon) between continents (Table 8). The occurrence of closely related species pairs that overlap only partially, if at all, such as illustrated in Figure 17 is common in Europe and is probably the result of the range of an original species being split in two by the great climatic fluctuations of the Pliocene and Pleistocene. The Great Plains of North America are another zone in which such pairs of species meet.

Centers of Endemism

The ranges of 27% of the species of land birds in the world extend less than 50,000 km². Such restricted-range species tend to occur in particular areas: Some 221 “endemic bird areas” (EBAs), each with two or more restricted-range species, have been identified. The concentration is such that 2% of the earth's land surface contains 20% of the bird species. The

tropics contain 76% of the EBAs but this may be no more than a reflection of the generally high species diversity in the tropics. Reflecting the importance of isolation in speciation, almost half of the EBAs are on islands, half of which are small and oceanic. Continental EBAs are often in mountainous regions, where both mountains and valleys can form barriers to the dispersal of species that are limited to particular altitudes. Other centers of endemism are less obviously isolated and it is often postulated that they are places that formed habitat

islands in the past as climatic changes fragmented their currently more continuous habitat. Since it is wooded rather than open habitats that tend to have been broken into such habitat islands, this fits with 71% of the restricted-range species being forest birds (and another 13% being birds of dry woodland and scrub). Alternatively, rivers and hills may be sufficient barriers to dispersal that they create the boundaries to centers of endemism.

Biogeographic Regions

Information on birds was important in the original identification of the six biogeographic regions of the earth — regions characterized by individual peculiarities of their faunas and floras as a result of long periods of separation in the past. Some bird families are found in several regions but others are confined to just one. The level of endemism in a region corresponds to the extent of its past isolation.

The least isolated regions, in that they form two great landmasses that have been joined by a broad land bridge (at the Bering Straits) for much of their recent history, are the Nearctic (North America) and Palearctic (Europe, most of Asia, and North Africa). The first has no endemic bird families and the second only one; many families occur in both, probably as a result of invasions from the Palearctic to the Nearctic via the Bering land bridge. The climate is markedly seasonal in large parts of each of these regions and they support comparatively few species (approximately 750 in the Nearctic and approximately 1100 in the Palearctic), many of which are migrant insectivores that move south in winter. Many species were probably lost from these regions as a result of deterioration of the climate during the Pleistocene. Subsequently, the Caribbean Sea, the Mediterranean Sea, and the Sahara desert, although crossed by many migrants, have been partial barriers to recolonization from Africa and South America.

The Oriental region (the Indian subcontinent and South-east Asia) has only 1 endemic bird family, although it remains somewhat isolated from the Palearctic by mountains. It has approximately 1000 species. Much of its avifauna originated largely in the Palearctic, although it has some affinities with the Ethiopian region (sub-Saharan Africa). The latter has 13 endemic families among its approximately 1500 species. It receives many Palearctic migrants during the northern winter and some of its resident species may have ancestrally originated in the Palearctic. The richness of forest birds in Africa is

Figure 17 Ranges of nightingale *Luscinia megarhynchos* (dark shade) and sprosser *L. luscinia* (pale shade) in the breeding season (northern) and in winter (southern). Black areas show where the ranges overlap (redrawn from Cramp S (ed.) (1988) *The Birds of the Western Palearctic*, vol. 5: Oxford: Oxford Univ. Press).

less than that of Central and South America, perhaps reflecting the disruption to African forests caused by dry periods in the Pliocene and Pleistocene.

The Australian region has a distinct avifauna—16 endemic families and approximately 1000 endemic species among the approximately 1600 bird species living there. Many of these belong to the Corvidae, a major division of the Passeriformes revealed by DNA analysis, which appears to have originated in Australia. New Guinea and other nearby islands belong to this region, the somewhat unclear dividing line between the Australian and the Oriental regions lying between Lombok and Bali and between Celebes and Borneo, along a deep strait that has probably always separated these regions even when sea levels have been much lower than they are today. The ancestors of some Australian species have arrived from the north across this barrier, but others are derived from the south, at a time when Australia lay with the other Southern Hemisphere continents in the great landmass of Gondwanaland.

The most distinctive and most species-rich region is the Nearctic (South America), inhabited by 31 endemic families and more than 3000 species living in a variety of habitats ranging from the tropical to the far south temperate and from sea level to extensive mountains. It has a comparatively small proportion of oscines among its avifauna and seems to have had a long evolutionary independence from the rest of the world, although its passerines may be largely derived from North America.

Evolutionary Convergence

When unrelated forms occupy similar habitats in different parts of the world, they may evolve similar characteristics in adaptation to those habitats. Such evolutionary convergence between unrelated forms is widespread among birds: for example, the great auk *A. impennis* and penguins (large, flightless seabirds using wings to swim under water); the little auk *Plautus alle* and diving petrels *Pelecanoides* (small seabirds that plunge into the depths to catch planktonic prey, using wings to both swim and fly); the New World vultures (related to storks) and the Old World vultures (related to hawks); the horn-bills and toucans of the Old and New Worlds, respectively (both with long bills for reaching fruit in the canopy, with secondary use of the decorated bill for social signaling); and the sunbirds and the hummingbirds, also of the Old and New Worlds, respectively (small, brightly colored nectar feeders, with specialized tongues). More generally, the Australian Corvidae include many groups of birds that have been considered in the past to be more closely related to various groups of passerines elsewhere in the world than to each other. Such conclusions depended on similarities that they shared with these other groups as a result of occupying similar ecological niches and thus being molded by similar selection pressures. These similarities are now recognized as convergent.

The extent of morphological convergence among whole communities has rarely been examined. A comparison of birds from Mediterranean communities in France, California, and Chile showed that they were no more similar to each other than each was to bird communities from a temperate part of France. Perhaps the environmental differences between

temperate and Mediterranean France are too slight to promote significant morphological divergence.

Diversity on Islands

The Colonization of Islands by Birds

Seabirds abound on islands partly because they are safer places to nest than mainlands (generally having fewer predators) but also because the oceans present no barriers to seabirds. In contrast, land and freshwater birds are less diverse on islands than on mainlands, although they have been much more successful in reaching islands than have other nonmarine vertebrates. Continental islands, which were once joined to larger land-masses before being separated by continental drift or sea-level rise, may retain some of their original species (perhaps much modified) but the evidence indicates that the more ancient of them have been colonized by many other species across the sea. Recent genetic evidence that kiwis are related to emus suggests, for example, that their ancestors may have arrived from the north, perhaps by flying over the Tasman Sea. (Moa, in contrast, probably originate from an original Gondwanaland stock.) Oceanic islands, never joined to a mainland, must have been colonized over the sea. Vagrant individuals of a variety of species are commonly observed even on the most remote islands. The efficacy of such colonization is shown by the fact that those islands of Krakatau that were devastated by volcanic eruption in 1883 held as full a complement of species as undisturbed islands within less than 100 years. As another example, if one allows for differences in area (small islands tend to hold fewer species), oceanic islands are as rich in bird species as continental islands in the Gulf of California.

Even for birds, however, isolation appears to result in substantial loss of diversity (Figure 18). Islands 250 km from New Guinea have only about half the number of bird species expected from their size, and those more than 800 km away have fewer than 10%. However, is this because birds do not reach remote islands? Perhaps they get there but do not find rich enough habitats (because a sufficient wealth of plants and other animals has not arrived). The answer undoubtedly depends on the species and the island in question. Studies that focus on individual species, rather than just on counts of species number, show clearly that species differ markedly in colonizing ability. J. M. Diamond conducted extensive analyses of the bird faunas of the many satellite islands of New Guinea and found, in addition to simple distance effects, that islands that were connected by land bridges during periods of low sea level in the Pleistocene had more bird species than those that had not had such connections. Some species, apparently poor at crossing water, are found only on land-bridge islands, even though the never-connected islands have the same habitats available. Diamond divided the birds according to apparent colonizing ability. At one extreme are “super-tramps,” often seen as vagrants, found on the most isolated islands that few other species have colonized, living at high densities, breeding rapidly, and having unspecialized habitat requirements. At the other extreme are species that are found only on islands that many other species have also reached;

Figure 18 Relationship between the number of species on individual islands in the warmer seas and their areas. Circles represent islands more than 300 km from the next largest landmass or in the Hawaiian or Galapagos archipelagos (redrawn from Williamson M (1981) *Island Populations*. Oxford: Oxford Univ. Press).

they are habitat specialists and live at low densities. When they reach an island these specialists appear to reduce the resources to such a degree that the generalist super-tramps cannot survive; the latter are therefore absent from species-rich islands. Thus, the supertramp dove *Ptilinopus solomonensis*, found on many small islands of the Bismarck Archipelago, is replaced on New Britain and New Ireland by three congeners—one in mountains, one in lowland forests, and the third in open lowland habitats.

Evolution of Island Birds

Island populations are genetically somewhat isolated (sometimes wholly isolated) from the mainland populations from which they sprang. The environment on the island is likely to differ from that on the mainland both physically and biotically (having fewer competitors and predators). As a result, there may be rapid evolutionary adjustment. Flightlessness has already been mentioned. Niches may be broadened. Thus, in most of western Europe, treecreepers *Certhia familiaris* are largely confined to conifers (and generally to high altitudes) by the presence of the closely related *C. brachydactyla*, which is a broad-leaved specialist, but in Britain and Ireland (and also in far eastern Europe and Asia), from which *C. brachydactyla* is absent, they inhabit woods of all sorts. Where studies of the relationship between bird species diversity and foliage height diversity have been conducted on islands, it has been found that the birds appear to divide the foliage into fewer layers than on the mainland; individual species have broader niches when there are fewer competitors. Another evolutionary change in some groups, such as ducks, is that island forms may lack distinctive male breeding plumages, either because there is less chance of hybridization when related species are absent or because demographic changes lead to behavioral modifications.

Island forms are often recognized as subspecies as a result of such changes; they may even become distinct species.

The chaffinch *Fringilla coelebs* is widespread in Europe and North Africa, inhabiting both deciduous and coniferous woods. It has the same habits on the Canary Islands of Hierra and La Palma, but on Tenerife and Gran Canaria it is restricted to deciduous woods; coniferous woods on those islands are occupied by the related *F. teydea*. These islands appear to have been colonized by *F. coelebs*, which then, adapting to the widespread coniferous woodlands there, evolved so much (into *F. teydea*) that when another *F. coelebs* invasion occurred the two species not only failed to interbreed but also each had a habitat to which it was better suited than the other and in which it could therefore persist. Such species pairs are known elsewhere. They represent a rare case of island bird communities being more diverse than those of mainlands.

Studying the birds of the Lesser Antilles, R. E. Ricklefs and G. W. Cox modified the idea of a "taxon cycle," earlier propounded by E. O. Wilson in respect of Australasian ants to describe the distributional and evolutionary changes when a species colonizes an archipelago. *Molothrus bonairiensis*, progressively colonizing the southern islands (from South America), represents an early stage of such a cycle; *Tyrannus dominicensis*, found throughout the islands, represents the next; and then *Loxigilla noctis*, with distinct subspecies on some islands. Finally, some of the islands have actually lost the colonizing species, either through chance extinction or through competition from later invaders: *Dendroica adelaidae*, restricted to St. Lucia and Barbuda, is one such species.

Isolated archipelagos, with very depauperate faunas but diverse habitats and with some isolation between islands, are hotbeds of evolution for those species that do arrive. The adaptive radiation of the Hawaiian honey-creepers (Drepanididae) is a well-known example. Comprising 23 extant species (more than half the endemic bird species on Hawaii) and at least 8 extinct ones, they are derived from a single fringillid

ancestor but with remarkably divergent feeding adaptations: typical finch beaks for seed-eating, parrot-like beaks, thin insect-eating beaks, and beaks elongated up to one-third the body length for sucking nectar. The akiapolaau *Hemignathus wilsoni* has a stout lower mandible with which it chips into decaying wood, holding out of the way its long, curved upper mandible, which it then uses to probe for insects in the exposed galleries. Darwin's finches (Geospizinae) are even better known. The diversity of the Galapagos species of this subfamily is in sharp contrast to the existence of just 1 species on Cocos Island, about 700 km northeast. The latter, although it has a diversity of habitats, has not presented the opportunities for speciation that the many separate islands of the Galapagos have done; as a result, the Cocos finch is behaviorally flexible, utilizing a wide range of foraging opportunities.

The Species–Area Relationship in Birds

It is well-known that larger islands tend to hold more species (see Figure 18). Birds have been used in many studies of the species-area relationship because they have reached most islands and their distributions are well-known. An especially steep relationship has been observed for islands in a Minnesota lake, apparently because the smaller islands studied were just too small (<0.5 ha) to support even single territories of many species. However, this is unlikely to account for the relationship observed in many studies of much larger islands. This has been widely interpreted in terms of the MacArthur–Wilson theory of island biogeography: As more species become established on an island, the rate at which new species colonize is bound to decrease (fewer of the arrivals are of new species); as the number of established species increases, the number going extinct also increases (there are more to go extinct); and at some point the colonizations and extinctions therefore reach an equilibrium. Since extinctions are less likely on larger islands (because populations are larger), the equilibrium number of species will be greater on larger islands. On well-studied islands, such as those around the British coast, there are certainly frequent colonizations and extinctions. These British islands are close to the source of colonists and are small, so this result is scarcely surprising, but it illustrates the dynamic nature of island avifaunas. The data also show that species differ in their probabilities of extinction; therefore, species-specific approaches are needed for a complete understanding.

The slope of the species–area relationship tends to be flatter for more isolated island groups because these are colonized only by the species with better powers of dispersal, which can quickly reoccupy islands from which they have gone extinct. On Bahamian islands, the slope is shallower for migrant species than for residents, the former being better colonists (and the slope is steeper for lizards, which are poor colonizers).

For species late in the taxon cycle, where extinctions have begun to take effect, the slope is steeper than for species early in the cycle, as the equilibrium theory would predict. Conversely, the slope was found to flatten in a group of Finnish islands following reduction in disturbance by man;

this had previously led to many extinctions, especially on small islands.

Although these observations are in agreement with the equilibrium theory, they do not rule out the importance of habitat. David Lack argued that larger islands held more bird species because they were more diverse, both physically and in terms of floristic richness. Statistical analyses designed to untangle the effects of habitat diversity and those of area *per se* found the former to be the chief cause of the species–area relationship in birds on the Isles of Scilly and on montane “islands” in the American Great Basin. Species richness of birds on the Lesser Antilles correlates independently with both habitat and area; in divergent contrast, bats correlate only with area and butterflies, reptiles, and amphibians only with habitat. It has been suggested that the difference is the result of birds (and bats *a fortiori*) having lower population densities than the other animals and therefore being more vulnerable to chance extinction. Similarly, the low species richness of the most isolated Bahamian islands seems to depend on both their isolation (many birds do not get there) and their habitat poverty (many arrivals find nowhere to live). Studies of forest fragments, which show the same sort of species–area relationship, indicate that part of the reason for the small number of species in small fragments is that they lack those species that are only found deep in forests.

Competition and resources mold island avifaunas. There is evidence that the species–area relationship is less steep for individual trophic groups than for whole avifaunas, which is in agreement with the idea that competition within the group reduces the ability of new species to colonize when an island already has many species or increases the likelihood of a new colonization leading to the extinction of an established competitor. Competition may also explain the paradoxical finding that migrant birds are more species rich on more remote Bahamian islands; the migrants, it is hypothesized, can reach all the islands but are less likely to establish on islands with residents already established (i.e., the less isolated islands).

Fragmentation as a Cause of Extinction

Nature has conducted experiments that reveal the importance of the area of islands in determining extinction rates and thus the numbers of species present at equilibrium. Thus, islands that were connected to New Guinea as a result of lower sea levels approximately 10,000 years ago now have fewer species than expected if they were part of mainland New Guinea (although they still have more species than do islands of comparable size that were never connected, suggesting that equilibrium has not yet been reached). Three New Guinean islands that were part of a single island approximately 10,000 years ago have fewer species than that single island would be expected to have, given its estimated size (although again they have more than expected for islands of their current size). The number of species that each has apparently lost is inversely proportional to its area, as the equilibrium theory predicts. The same is true for a suite of islands off the north coast of South America and the coast of Central America.

Man formed Barro Colorado Island during the construction of the Panama Canal early in the twentieth century. It has subsequently lost 50–60 species. Some of the losses may be the result of increased predation because man no longer hunts small and medium predators. It is striking, however, that the species that have gone extinct are those whose numbers appear to be particularly affected by the occasional periods of very dry weather that occur in the region. Average low population densities, in contrast, seem not to be a good predictor of extinction from Barro Colorado: As long as a population does not fluctuate too much, it can persist even if its average numbers are small.

Forests in most parts of the world have been fragmented by man and numerous studies have shown that fragmentation has resulted in the loss of species. This is not just the effect of random extinction, however, because it particularly involves the loss of forest-interior specialists. Indeed, direct observation in the highly fragmented woodlands of eastern England confirms that many more woodland species pass through small woodlots than stay to breed, showing that they would have no difficulty in colonizing such places if they were suitable. Blue tits *P. caeruleus* and great tits *P. major* breeding in such small woods produce fewer young, partly as a result of breeding later in the season, than do the same species breeding in larger woods. This may be because the small woods provide less shelter from the weather or because they lack sufficiently rich vegetation to produce adequate insect food for the birds. Whatever the cause, these fragmented woods support fewer birds than would a solid block of forest of the same total area.

In North America, Neotropical migrants also tend to avoid fragmented forests, much more than do resident species or temperate migrants. The fragmentation of forests may be the reason why so many Neotropical migrants have declined in numbers in recent decades.

Introduced Species as Colonists: A Challenge to the Equilibrium Theory?

Many birds have been introduced outside their native ranges and have flourished in their new homes. For example, 34 introduced land and freshwater species are established on New Zealand. Many of these have colonized offshore islands—up to 10 on a single island. This does not mean that those islands were not in equilibrium before these species arrived. What has happened is that the pool of species available to colonize the islands has been increased, raising the colonization rate and thus setting a new equilibrium.

If New Zealand were capable of absorbing these species, does this mean that it was not at equilibrium? With only 60

resident, nonmarine indigenous species it was certainly depauperate, so one could argue that ecological niches were vacant. However, in undertaking the introductions, man was enhancing the colonization rate, thus shifting the equilibrium upward. Furthermore, many native species have been driven close to extinction in New Zealand, with some surviving only because of special protection measures. Although habitat loss and the devastations of introduced predators have been major causes of such near losses, competition from the introduced species may also have played a part.

Human Causes of the Loss of Avian Biodiversity

Natural Causes of the Loss of Avian Biodiversity

The paleontological record shows that many birds have become extinct as part of the natural flux of life on Earth. The recent extinctions of an unnamed megapode on the Kermadec Islands (1876) and of the San Benedicto rock wren *Salpinctes obsoletus exsul* (1952) were also natural, resulting from volcanic eruptions. That element of biodiversity that is made up of the differences between regions in the species that inhabit them must also have been eroded by natural colonizations. These natural processes, however, are slow—slow enough for extinctions to be approximately balanced by the origins of new species. Man has accelerated them manyfold, causing serious losses of avian biodiversity.

The History of Bird Extinctions

It is difficult to be sure whether a species has gone extinct, especially if it is scarce and lives in remote places. The Fiji petrel *Pterodroma macgillivrayi*, for example, was known from but a single specimen taken in 1855 until a second was found in 1984. With that caveat, **Table 9** shows the avian extinctions recorded in the past 400 years. These represent more than 1% of known birds, a proportion similar to that for mammals but otherwise greater than that for any other group of animals or plants.

Two things stand out from **Table 9**. First, extinctions peaked between 1850 and 1950 but have still continued at a high rate. Second, approximately 90% of them have been extinctions of island species, even though only 20% of bird species live on islands. One-third of the birds present on Hawaii 200 years ago are now extinct and two-thirds of the remainder are endangered. Two-thirds of the historically indigenous birds of the Mascarenes have been lost and more than 40% of the rest are endangered. Island species are partly vulnerable because their ranges are so small and some of the

extinctions on continents have been of species with particularly small ranges. Because birds that occur in few places tend to be uncommon even where they do occur (Figures 5 and 6), they are especially vulnerable.

Hunting has caused many extinctions. As recently as 1945, Japanese troops eliminated the Wake Island rail *Rallus wakensis*. The case of the passenger pigeon *Ectopistes migratorius* is classic. Once numbered in hundreds of millions, it occurred in huge flocks that “darkened the skies.” Although habitat loss may have contributed to its decline, there is little doubt that it was extinguished by massive commercial hunting. Such uncontrolled exploitation contrasts with situations in which a community has been able to control the hunting, such as was the case on St. Kilda, where seabirds were a major resource whose exploitation was regulated. The great auk *A. impennis* and Dodo *Raphus cucullatus*, extinguished by visitors to their uninhabited island homes, provide a clear contrast and also illustrate other aspects of the vulnerability of many island birds: They were large, flightless, and had limited antipredator responses, thus making them easy and profitable to hunt. They probably had low reproductive rates and therefore were incapable of sustaining high levels of hunting.

The introduction of alien species has been a major cause of island extinctions. Worldwide, there is a clear correlation between the number of indigenous birds that have become extinct in a locality and the number of avian introductions established there. Some introduced species, especially mammals such as rats, cats, dogs, mongooses, and pigs, are important as predators. In the early 1960s, black rats *Rattus rattus* eliminated the last known population of the bush wren *Xenicus longipes* within 3 years of reaching Big South Cape Island, New Zealand, along with the island’s populations of four other birds. In 1894, the lighthouse keeper’s cat caught 15 Stephen Island wrens *Xenicus lyalli*; these were the first specimens discovered—and also the last. Introduced monkeys are important predators at the nests of endemic birds on Mauritius. Only one introduced snake is known to have caused serious problems, but its effects have been dramatic: The brown tree snake *Boiga irregularis* seems to have arrived on Guam in the 1940s as an accidental hitchhiker. By 1986 it had extinguished six of the indigenous forest birds and reduced the other four to populations of less than 100; of these, the endemic Guam rail *Rallus owstoni* had been reduced to 100 in 1983 and it was extinct in the wild by 1987, although it survives in captivity. In contrast, none of the seven introduced birds on Guam has been obviously affected by the snake: They have effective antipredator behavior and live in habitats in which the snake is scarce. (Only one of the eight native species in such habitats has gone extinct.) It is noteworthy that few of the species extinguished by introduced predators lived on islands with indigenous rats or land crabs, which would have caused them to maintain their antipredator responses.

Introduced birds may out-compete natives, especially in the modified habitats that man has created on most islands since they may be adapted to such habitats in their own native ranges. Thus, the familiar birds in suburban and agricultural habitats of New Zealand are the familiar birds in suburban and agricultural habitats of western Europe. Competition may be genetic as well as ecological: Part of the cause

of the extinction of the Atitlán grebe *Podilymbus gigas* may have been hybridization with the introduced pied-billed grebe *P. podiceps*.

The loss of natural habitats has been another major cause of extinctions. Much of it has been deliberate (the clearance of land for agriculture or human settlement), but much has been an accidental by-product of the introduction of alien herbivores, especially to islands where the native plants have evolved in the absence of such animals. Thus, the rabbit *Oryctolagus cuniculus* destroyed much of the vegetation on Laysan in the 20 years following its introduction in 1903; three of the five species of land birds disappeared with the plants. On some islands, soil erosion, following deforestation, has removed nest sites for burrowing seabirds.

Finally, the impact of introduced diseases is largely unknown but native Hawaiian species, previously free of avian malaria, have been infected via introduced birds.

The Recent Prehistory of Bird Extinctions

It is well established that there were mass extinctions of large mammals following the colonization of continents by man the hunter. Vulnerable birds may have been extinguished at the same time, as may have birds dependent on the mammals. Fossils show the Californian condor *Gymnogyps californianus* once to have been widespread across North America, its restriction to the west presumably consequent on the reduction in numbers of large mammals brought about by man, dating from approximately 11,000 years ago. It now survives only through a captive breeding program, its final historical collapse also being a by-product of human activity—in this case, poisoning by the lead in carcasses abandoned by hunters and by poisons used to kill coyotes *Canis latrans*.

Colonization of islands mostly occurred later. In the Pacific, people had gone as far as the Solomon Islands by 30,000 years ago but did not reach western Melanesia and Micronesia until 4000 years ago, moving then through Fiji and Samoa, the Marquesas, Hawaii, and Easter Island, with New Zealand only colonized about 1000 A.D. European colonists followed in the sixteenth-eighteenth centuries. Some of these human colonizations eventually failed, perhaps because of their dramatic impact on the islands’ ecosystems. The early colonists hunted the animals they found, generally introduced alien species, and usually cleared forests. Their activities certainly led to loss of bird populations: On Hawaii, 60 endemic species are known only from bones; at just one site in New Zealand, 29 endemics are known only from bones; on Easter Island, bones of about 30 species of seabirds have been found from the early years of human occupation but only 1 is now found there (with about 10 others surviving on offshore islets) and all the indigenous land birds seem to have died out following the total deforestation of the island. D. W. Steadman reached the following conclusions about Polynesian land birds:

- (i) The ranges of most living species are much smaller today than they were at the time of first human contact.
- (ii) Few volant species are naturally endemic to only one or two islands.
- (iii) Most species have become extinct in

the past 3000 years. (iv) Most or all islands supported one to four endemic species of flightless rails, virtually all now extinct. (v) In many cases, individual islands supported two or three species within a genus, unlike the situation today. (vi) At least four formerly widespread genera now are gone from East Polynesia. (vii) Although modern distributions of Polynesian land birds continue to be analyzed as if they were natural, they do not furnish unbiased data for proposing or testing ecological models. (viii) Although some of the range losses of extant species could be restored with conservation efforts, we are centuries too late to preserve any true likeness to the original Polynesian avifauna.

On the basis of the fossil evidence, Steadman suggests that the 800 Polynesian islands inhabited by man have lost an average of 10 species or populations of birds, including 2 or 3 species of flightless rails endemic to each. Other authors have suggested that, because of the incompleteness of the fossil record, even these data may be underestimates. Whatever the details, the avifauna that survived to be further devastated by Europeans, Americans, and Japanese was a small part of that which the earlier colonists found. The marked deficiency of seabirds in the tropics, although probably partly a result of the low productivity of tropical oceans, may be a legacy of this destruction.

Current Threats to Birds

On the basis that they have undergone (or appear likely soon to undergo) rapid declines, that they have small and declining populations, that they leave small and declining ranges, or that they have very small populations, 11% of the species of birds in the world are classed as "threatened." The percentage for mammals is similar; no other group of animals reaches this level of threat. Forest birds make up 65% of this total, and those of scrub and of wetlands each comprise 9%.

Most of the endangered species are tropical. At least for the New World, this is not just because there are more species in the tropics because the proportion of the avifauna that is threatened is also highest in the tropics (Figure 19). This appears to be in part because the tropics hold many species with restricted ranges. (Throughout the world, about one-fourth of the threatened species are endangered simply by having very small populations or ranges.) In the New World, it is also because of the intensity of tropical deforestation. Of course, areas that hold relatively few threatened species may do so because those species that were especially vulnerable to the impact of man have already gone extinct; this may explain why there are fewer threatened species north of the equator in the Americas than in the south (Figure 19), given the longer history of human interference in the north.

Habitat loss, especially the loss of tropical broad-leaved forest, is a threat to about half of the world's endangered birds. It is caused not only by the expansion of agriculture but also by mining and the construction of dams. In many parts of the world, afforestation with exotic species is a major problem: Being exotics, the introduced species offer homes to only some of the native animals. Furthermore, they are managed in ways that reduce the floristic and structural diversity of the

Figure 19 Proportion of New World birds classed as threatened, in relation to latitude (negative values are in the Northern Hemisphere). The horizontal line is the mean proportion threatened (redrawn from Gaston KJ and Blackburn TM (1996) The spatial distribution of threatened species: macroscales and New World birds. *Proc. R. Soc. London B* 263: 235–240).

plantations. Drainage of wetlands is a major problem in many regions, although one that can often be relatively easily reversed if there is the will to do so. About 8% of the world's endangered species are threatened by hunting and capture for the pet trade. In Europe, more than 30% of the species that have declined in recent years are thought to be affected by hunting or by related persecution (such as the killing of raptors that are viewed to be competitors with man). Much hunting is now recreational rather than for subsistence, but it is often more destructive than formerly because there are more people, because more of them have the leisure time to engage in hunting, because there is better technology (mist nets, guns, and motor transport), and because more people can afford the technology. Coastal habitats in sunny places are steadily being destroyed by the development of tourist facilities. Even where beaches are left in a natural state, birds breeding on them suffer from increased disturbance.

In Europe, the greatest threat, affecting more than 40% of declining species, is the intensification of agriculture. Birds of the steppes are threatened by irrigation, whereas those of wet meadows are threatened by drainage. Fewer resources are available for wildlife when hay meadows are converted to silage and when stocking rates on pastures are increased. Insecticides and herbicides remove much potential bird food from crops. Plant breeding, the use of pre-emergence herbicides, and more effective machinery may allow autumn cultivation in areas where fields used to be left in stubble over winter, such that granivores could feed on grain spilled at harvest and on the seeds of weeds. Harvesting is more efficient. Fundamentally, more of the primary productivity is being harvested, so less is available for wildlife. Most of these changes depend on technological developments but their adoption has been promoted by systems of agricultural support, such as the Common Agricultural Policy of the European Union (EU), that concentrate on production rather than also taking account of social and conservation needs. Expansion of the EU to include countries

of Eastern Europe, where agriculture is still relatively less intensive, is a major threat to birds and other wildlife.

Further agricultural changes may flow not only from technology and policy but also from global climate change. This will also affect natural habitats. Although vegetation and wildlife have adapted to the natural climate changes of the past 10,000 years, often apparently within decades, there are concerns that the changes now occurring will be substantially more disruptive because of their speed.

Reducing the Threats

Species have been pulled back from the brink. Use of DDT reduced the Mauritius kestrel to 4 birds in 1974 but 20 years later, through a program of captive breeding and reintroduction, there were more than 200. There have been several similar cases, but they have required very intensive care. More extensive measures are needed if all threatened birds are to be conserved.

There are two broad approaches to such conservation. One is simply to control all of the threats listed previously, which would have a widespread impact. Some actions would be neither politically very difficult nor economically very costly, such as banning deliberate introductions, controlling accidental introductions, and eliminating introduced species that have become established. Most, however, would entail a direct conflict between the benefits to wildlife and the material wealth of burgeoning human populations.

The other remedy is to secure individual sites as biodiversity reserves. This would also be expensive because, although 20% of bird species occupy just 2% of the land surface of Earth, it would take a much larger area to include the other 80%. (Furthermore, because hot spots of diversity for different taxa do not closely coincide, even greater areas would be needed if more than birds were to be considered.) In any case, diversity hot spots are peculiar places; conserving them might maintain many species but it would not conserve the natural diversity of ecosystems. There is also the practical difficulty of

ensuring that the correct locations are chosen. For example, after decades of trying to build up numbers of the red kite *Milvus milvus* in the Welsh fastnesses to which the British population had become restricted by nineteenth century persecution, conservationists concluded that it was probably in Wales not because the most suitable habitat was there but just because it had not been shot out there; populations subsequently introduced to eastern England and Scotland have flourished, indicating that the Welsh birds were probably living in relatively poor conditions.

Other Reductions in Local Diversity

Extinction is a particularly obvious way in which biodiversity is diminished but is merely the tip of an iceberg. For every species extinguished by man, there are many others whose numbers and ranges are substantially reduced. (There are also a few whose numbers have been much increased by human activity, such as the house sparrow *Paaser domesticus* and starling *S. vulgaris*.) Changes in numbers are less easy to assess than extinctions and little is known about them in many parts of the world. There are good data, however, for much of North America, where it is clear that recent decades have seen major declines of many Neotropical migrants. It is not clear to what extent this is the result of habitat loss in the wintering areas or of fragmentation of woodlands on the breeding grounds. In Europe, changes in agriculture have been closely followed by declines in the populations of farmland bird specialists (Figure 20). Studies of individual species are beginning to reveal the causes of these losses, which are different in detail for different species but all fundamentally related to agricultural intensification.

It is specious to argue that such changes are but a reflection of the natural flux of populations. Although systematic counts are not available for most species, except for recent years, it is clear from the extensive historical literature that British farmland birds have probably never before suffered losses on the

Figure 20 Index of bird populations in the United Kingdom based on geometric means of indices for individual species. Introduced species and those with fewer than 500 pairs are excluded (reproduced from the British Trust for Ornithology and the Royal Society for the Protection of Birds).

scale of those recorded in the past few decades, even during the periods of enclosure and other intensive habitat modification near the end of the eighteenth century and the development of high agriculture in the nineteenth century. The argument that the species characteristic of farmland are much more common than they were before much of western Europe was cleared of its forests is correct but incomplete. Forest clearance led to open-country birds replacing woodland birds, but the farmland birds now being lost are not being replaced. As a result, the total biomass of nonmarine birds breeding in Great Britain declined between 1968 and 1988 by 10% (39% if the pheasant *Phasianus colchicus*, which is widely and increasingly stocked for shooting, is omitted).

Losses of Geographical Diversity

Part of the diversity of life on Earth is the difference between places in their animal and plant communities. Introductions not only endanger biodiversity at the local scale (see Human Causes of the Loss of Avian Biodiversity – The History of Bird Extinctions and Human Causes of the Loss of Avian Biodiversity – The Recent Prehistory of Bird Extinctions) but also, however harmless they are to the indigenous fauna and flora, lessen biodiversity by reducing the difference between places.

More than 130 species of birds have been naturalized outside their native ranges, i.e., they have been introduced and have established breeding populations. As a result, the range of some species has increased dramatically. The pheasant *Phasianus colchicus*, native in only a band stretching from the Caucasus to Japan, now occurs in most of Europe, temperate North America, and New Zealand, with scattered populations in Australia and various islands.

Sport is a major reason for introductions (even in regions with plenty of native game birds) and one-fifth of established introductions are of pheasants (Phasianidae). Some species have been introduced for food (such as the feral pigeon *Columba livia*), many to remind settlers of “home” (such as European songbirds across the globe), and some because they are beautiful (e.g., peafowl *Pavo cristatus*). Some have been introduced as agents of biological control, such as the house sparrows *P. domesticus* transported to the United States in the nineteenth century to control defoliating moths. The Chimango caracara *Milvago chimango* was introduced to Easter Island as a scavenger. Conservationists have occasionally introduced threatened species beyond their native range because the latter was too badly affected by habitat destruction or by introduced predators or sometimes, perhaps less justifiably, because the native range was considered unsafely small.

Many species have established themselves following accidental escape from captivity; therefore, wildfowl, parrots, doves, and small seed eaters make up a high proportion of naturalized species. In the summer of 1991, Britain (which, like most of western Europe, has only one native species of goose) held established breeding populations of four other geese; 10 other species were at large, 2 of them recorded breeding, and there were 18 different sorts of hybrid geese identified. Some of these avicultural

species may be deliberately released because their owners tire of caring for them or wish to see them free-flying. Similarly, farmed species may be released if markets collapse: This is the origin of the Australian population of the ostrich *Struthio camellus*.

Species that are closely associated with man, such as house sparrows and house crows *Corvus splendens*, have reached some places by riding on ships.

Introductions of birds have been less damaging than those of mammals and fishes. Nonetheless, each one of them represents a direct reduction in the diversity of life throughout the world.

Glossary

Basal rate of metabolism The minimum amount of energy spent by an adult animal that has not eaten recently, at normal body temperature during rest (usually sleep).

Eutherian Mammal in which the embryo is attached to the mother by a placenta.

Fissipedia Suborder of the Carnivora with divided toes.

Guild Species in a community that use similar resources.

Marsupial Mammal without placenta and with a pouch to carry the young.

Monophyletic Derived from a single ancestor.

Pinnipedia Suborder of the Carnivora with fin-like limbs (seals, sea lions, and walrus).

Plantigrade Walking on the soles of the feet.

Species Diversity

Among the mammals that are broadly referred to as Carnivores there is a weasel of approximately 45 g and a polar bear of up to 700 kg, approximately 15,000 times heavier. There are species living almost permanently in water (sea otter), in trees (palm civet), or in deserts (fennec fox); some eat buffaloes, some eat beetles, and some eat bamboo. It is not surprising, therefore, that with such large variation and divergent adaptive features there is disagreement among researchers about the evolution and classification of species. Classification is based on morphological evidence (dental characteristics, anatomy of the skull base, and other morphological features) and on molecular genetic information.

This article will deal with the approximately 230 Fissiped carnivores, i.e., the terrestrial species of the order Carnivora and excluding the seals, sea lions, and walrus (Pinnipeds). It will also discuss a group of ecologically rather similar species of marsupials in Australia belonging to the families Dasyuridae and Thylacinidae.

The Carnivora are a monophyletic order, descended from the family Miacidae approximately 60 million years ago in the Palaeocene. The order has two main branches, the dog-like Canoidea and the cat-like Feloidea. The 33 seals and sea lions and walrus belonging to the Pinnipeds are sometimes included in the order Carnivora and sometimes given separate status. They evolved from the Canoidea, but there is disagreement about which terrestrial carnivores are their closest relatives, the main candidates being the bears and the mustelids.

The Carnivora are generally divided into seven families, although some taxonomists recognize more. The Canoidea include the Canidae (dogs) with 35 species, the Mustelidae (martens) as the largest carnivore family with 67 species, the Ursidae (bears and pandas) with 9 species, and the Procyonidae (raccoons) with 15 species. The Feloidea comprise the Felidae (cats) with 35 species, the Hyaenidae with 4 species, and the Viverridae (mongooses and genets) with 66 species. The main taxonomic disagreements are over the Ursidae and the Viverridae. The two species of panda are often thought not to belong to the bears but to deserve a separate family or they may be

included with the Procyonidae, and the Viverridae are often divided into two families—the Herpestidae (mongooses, 31 species) and the Viverridae (genets and civets, 35 species).

The dogs and foxes (Canidae) constitute a highly monomorphic family. All are very dog-like with nonretractile claws, and all are coursing predators, such as wolves, coyote, jackals, foxes, wild dog, bush dog, and maned wolf. All species have much in common in their ecology and social behavior, although they may vary from solitary to gregarious. Sizes vary between that of the large gray wolf (up to 80 kg) to that of the tiny fennec fox of little more than 1 kg. Canids occur on all continents, and with the dingo they even fielded an early introduction in Australia. The gray wolf is the ancestor of all domestic dogs.

Eleven canids (31%) are endangered or vulnerable, and all the large species are threatened in at least some parts of the world (the two wolves, African wild dog, and the Asian dhole).

The members of the marten family or Mustelidae occur in both the New and the Old World, with weasels, martens, mink, polecats, skunks, otters, badgers, and others. There are relatively few species in Africa, perhaps because of competition with the similar viverrids. In Britain, there are three times as many mustelid species as members of all other carnivore families combined, and in the United States there are also more mustelids than others. Almost all are quite small animals (45 g to 45 kg), with the largest species being some of the 13 species of otters. They are usually slimly built, some with retractile claws, and with a very distinctive bouncing gait, but the family is quite variable and some species are stocky, such as the badgers. Also, in feeding and social behavior they vary greatly, from solitary predators on mammals to group-living animals feeding on earthworms or fish.

Stoats and weasels have been introduced on several islands outside their normal range, and the North American mink is now an abundant exotic in many places throughout Eurasia and South America. Some of the mustelids are almost extinct (e.g., the black-footed ferret and the European mink), some were exterminated recently (sea mink), and several are in trouble (otters) or have just returned from the brink of extinction (such as the largest of them all, the sea otter).

However, only seven species (10%) are listed as endangered or vulnerable.

The bears and pandas (Ursidae) are comparatively large and some are huge (weighing up to 700 kg), stockily built, plantigrade with nonretractile claws, and very short tails. The exception is the very aberrant red panda (a small arboreal species with a long tail), a species often classified as a procyonid. All but the polar bear are mostly vegetarian; they are solitary animals with a fairly simple social organization. The bears evolved more recently than the other carnivores and successfully colonized areas as far apart as the drift ice in the Arctic and the dense forests of the Old World and neotropics. Bears of colder regions hibernate. More than half of the species (five or 56%) are endangered or vulnerable, and all are in trouble in at least part of their geographic range.

Members of the raccoon family Procyonidae are all rather long-bodied animals, relatively small (up to 8 kg), with long, ringed tails, and they walk plantigrade with nonretractile claws. They occur naturally only in the New World. In addition to the various species of raccoon throughout the Americas, there are also other Neotropical species, such as the coatis, the kinkajou, and the acomistla. They are carnivorous and insectivorous as well as herbivorous. Their social behavior is quite variable; most are solitary but some, for example, female coatis, live in large packs. Also, common raccoons may occupy winter dens in groups. None are classified as endangered, although some raccoon species are known from only one or two islands, on which they may be rare. In several areas of Eurasia common raccoons are now frequent as an introduced species.

The Viverridae are a large Old World family of small animals, occurring almost entirely in Africa and Asia. They are the most "primitive" carnivores, i.e., the closest relatives of the carnivores' original forebears, the Miacidae. The family includes many species of genet and civet, linsang, binturong, a large range of mongooses, meerkat, fossa, fanaloke, and others. Some taxonomists recognize the mongooses as a separate family—the Herpestidae (otherwise classified as a subfamily Herpestinae). The mongooses are long-bodied and look somewhat mustelid-like, with nonretractile claws; in contrast, the rest of the viverrids look and walk much more cat-like, with retractile claws. The fossa from Madagascar is unusually large (up to 20 kg), but all other Viverrids are much smaller, especially the mongooses. Most are solitary, but some mongooses and meerkats live in large packs. Most of their food is invertebrate, but they also take small mammals, etc. and occasional vegetable food.

Few viverrid species appear to be endangered (four or 6%); of these four, three are on Madagascar, an island beset by deforestation problems.

The Hyaenidae have only four species left, despite a fossil record showing large numbers in the geological past, and they occur only in the Old World. Three are relatively large species of 50 kg or more and are typical coursing animals with a dog-like build and nonretractile claws. Hyaenids are carnivorous; they often scavenge, although some also take vegetable food, and the smallest, the aardwolf, is a termite specialist. The largest species, the spotted hyena, is a gregarious hunter of large mammals, but the others are solitary. One of the four, the brown hyena, is classified as vulnerable as a species, but in many countries the others are also endangered.

Finally, there are the Felidae, the proper cats, a highly monomorphic family with many species. All are built as stalking predators, with retractile claws, and they range in size from fairly small to large, from serval and flat-headed cat and many other small species to lynx and tiger (up to more than 300 kg), various leopards, cheetah, and lion (up to 250 kg). All are carnivorous, but small species also eat many invertebrates. The social organization of all species is very similar—solitary and territorial, with the lion as the only group-living exception. Felids occur naturally on all continents except Antarctica and Australia. The wild cat *Felis lybica* has been domesticated and it has been introduced virtually everywhere in the world; it is now the most widespread carnivore.

There is concern about the conservation status of almost all cat species, especially the ones with desirable fur. Twelve (34%) are endangered or vulnerable, including all the large ones such as tiger, cheetah, jaguar, and various leopards, but not the lion.

The mammalian carnivore families outside the Carnivora proper are the Australian marsupials Dasyuridae and Thylacinidae. There are four dasyurid species that are very similar to Carnivora: three quolls or, as the Australians call them, "native cats" and the Tasmanian devil. They are relatively small, with the quolls similar in size and appearance to martens or mongooses and the Tasmanian devil more like a small badger in size and shape, and they are typically carnivorous, solitary, nonterritorial animals. The thylacine was the only species in its family and it was also the largest of these marsupial carnivores (comparable in size to a large jackal or coyote). It was exterminated very recently. The other, dasyurid species now have very much reduced geographical ranges and they are vulnerable.

Size and Ecology

There is a large diversity of sizes among carnivores, and the ecological implications of this variation are considerable. The basal rate of metabolism of carnivores tends to be greater than that of same-sized herbivores, and a large predator expends more energy than a small one; therefore, it has to capture more prey. However, the increase in metabolism with size is not linear, and when expressed as energy requirements per kilogram of body weight a large predator is more efficient than a small one (Figure 1).

The body mass of a carnivore, when combined with the group size in which it lives, is correlated with the size of its home range, although there is much variation (Figure 2). Much of this residual variation is due to effects of habitat and to differences in diet (predators of vertebrates having larger ranges than insectivorous ones). There is no significant correlation between body mass and gregariousness, i.e., large carnivores are no more likely to live in groups than are small ones.

Brain size of carnivores increases with body size. Irrespective of this, a meat-eating, hunting carnivore or an omnivorous species generally has a relatively larger brain than an insectivorous one. Bears have relatively large brains, whereas Viverrids and Hyaenids have relatively small ones and the others have intermediate-sized brains.

Figure 1 Basal rate of metabolism (oxygen consumption per gram per hour at rest) in carnivores as a function of body mass. Reprinted from McNab BK (1989) Basal rate of metabolism, body size, and food habits in the order Carnivora. In: Gittleman JL (ed.) *Carnivore Behavior, Ecology and Evolution*, pp. 335–354. Ithaca, NY: Cornell Univ. Press.

Figure 2 Home range size of carnivores as a function of metabolic needs. •, Canidae; ○, Ursidae; ■, Procyonidae; □, Ailuridae; ▲, Viverridae; △, Mustelidae; ◆, Felidae; ◇, Hyaenidae. Reproduced from Figure 1 in Gittleman JL and Harvey PH (1982). Carnivore home-range size, metabolic needs and ecology. *Behav. Ecol. Sociobiol.* 19: 57–63.

In general, large carnivores take larger prey than do small ones, but there are important variations. First, some of the largest (bears) are mostly vegetarian. Second, the trend varies between carnivore families. Within the mustelids there is a

nonsignificant negative correlation between predator body mass and prey size, so the predator–prey size principle does not apply. Both felids and canids show a strong positive correlation, but the slope of the relationship is different: The increase in prey size with predator body mass is much steeper in felids (Figure 3).

There are many specific deviations from the previously discussed general patterns, but the trends are significant. Greater energetic demands on larger carnivores are met by a dependence on larger prey, which is likely to make the large predators more vulnerable. Many of the larger carnivores are threatened globally or in parts of their range, e.g., many of the large spotted cats and the tiger, wolves, and hyenas.

Foraging and Phylogeny

The diet of carnivores in general, and that of their marsupial equivalents in Australia, consists of vertebrate prey but also invertebrates and vegetable matter. The order Carnivora shows dental specializations enabling easy digestion of vertebrates, such as large canines and the carnassial shear, but in several species the molars have been further adapted to a more grinding function when eating plants.

Foraging or hunting behavior of carnivores consists of variations on a general theme. A search leads to detection and selection of a potential victim or other source of food, and it is followed by an approach which may contain elements of stalking and/or chasing. The actual capture of prey may include seizure, immobilizing, and killing, and this is followed by eating, taking food to cubs, or sometimes quietly caching it for later consumption. Parts of this sequence may be absent, and in fact most carnivores will just search and then eat small food items without much further ado. However, even if there is a full-blooded hunt, some species never stalk (e.g., dogs or hyenas), others never chase (e.g., cats), and some may not show any specific killing behavior but just eat (e.g., hyenas).

The chain of events aimed at the capture of prey may be broken off at any stage depending on circumstances; it can

Figure 3 The relationship between size of predator and prey. For each species of carnivore, mean body weight and main food category are given. 1, invertebrates; 2, small rodents; 3, rabbits and hares; 4, larger mammals less than 50 kg; 5, mammals more than 50 kg. Reproduced from Kruuk H (1986) Interactions between Felidae and their prey species: A review. In: Miller SD and Everell DD (eds.) *Cats of the World: Biology, Conservation and Management*, pp. 353–373. Washington, D.C.: National Wildlife Federation.

also be started at any stage. It is highly adaptive, depending on prey and environment, with the predator's own motivation (its degree of hunger) apparently affecting especially the early searching stages of the hunting sequence.

Conspicuous in the predatory behavior of many carnivores is the phenomenon of surplus killing, i.e., killing more than is required for immediate consumption. Classic examples are the fox in the hen house or gull colony or a lion among a cattle herd; it has been described for hyenas, polar bears, wolves, leopard, and others. Large numbers of animals were killed without being eaten. All these situations have in common a lack of defense by the prey: The prey may be immobilized by particular weather conditions, it may be penned in, or it may have lost its antipredator defense through domestication. In these cases, the predator is sated and no longer hungry, but hunger normally affects only the early stages of the carnivore hunting sequence, especially the search. If, for some reason, no search or stalk or chase is needed because the hunter suddenly finds itself close to the quarry, then the rest of the hunting sequence is put in train irrespective of hunger, and there is no inhibition to capturing and killing. Functionally, such events are wasteful from the carnivore's point of view because they reduce prey availability without the predator getting the benefits.

Food caching (i.e., the storage of food in a hidden place) is a behavior pattern that limits this waste and utilizes the consequences of surplus killing. Many species do it, and do it in many different ways. In all canids it is highly stereotyped: A small hole is dug, and one single prey is dropped into it and covered with earth or vegetation by sweeps of the snout. In other families there are many variations on the caching theme: Leopards take a carcass high into a tree; spotted hyenas cache

chunks of food in shallow water; brown and striped hyenas push it into a dense bush; stoats, mink, and other mustelids may make large stores by dragging numbers of prey into a single hole; wildcats may put remains of their quarry under a log; and some of the larger cats may civer a carcass with vegetation. The methods are consistent within the species, for canids within the family, and for martens within the subfamily, suggesting that caching has evolved in carnivores on several different occasions. There is no evidence of caching for the procyonids or viverrids, nor is it done by the marsupial carnivores.

Although food caching may use some of the surplus kills, it still does not utilize all the apparent waste. Not only are some of the caches never revisited by the perpetrator but also in the larger surplus kills only a small proportion of the victims are stored. There may be scores of dead gulls left by a fox and of gazelle left by spotted hyenas. In some carnivores caching is particularly highly developed. For instance, foxes are able to remember where they stored what, and they return preferentially to the more desirable cached items. Foxes also use some kind of bookkeeping system for their caches, leaving a drop of smelly, long-lasting urine near those caches which they have emptied.

Foraging and hunting behaviors are features that differ with the phylogeny of the predator. Canids invariably are coursing and running predators, with an occasional semistalking approach of prey, and they often forage by "sniff and search." At the other extreme, felids search almost entirely dependent on vision and they approach their quarry in a highly concealed stalk or ambush. Most members of the other families, including the marsupial carnivores, show the canid sniff and search behavior pattern. Only the genets and civets have a stalking behavior that is similar to that of the felids.

When a relatively small vertebrate prey is caught, the felids, many of the mustelids, and civets will kill it by severing the spinal cord with their canines. Canids also have a specific killing method—violently shaking the prey. Felids kill large prey with a throat bite, or they suffocate it with a bite over the nose and mouth. In almost all other predator–prey interactions there is no specific killing or immobilizing behavior—the predator just eats the prey. Most species of carnivore have highly specific ways of dealing with a prey and its carcass, and it is often possible to distinguish afterwards which predator was responsible for a kill.

Some subfamilies have evolved extreme foraging specializations. The Lutrinae (otters) dive for fish and crabs using their tactile senses, but essentially their hunting is also based on the canid pattern. Several Melinae and Mellivorinae (badger) species pursue their prey by digging after it. Species such as the otters and African wild dogs use energetically demanding behavior to catch their quarry (a high investment and high reward strategy), which makes them especially vulnerable to fluctuations in prey density and to food loss to scavengers.

As a result of the variation in foraging methods between families and subfamilies, there are also phylogenetic patterns in the diet. Compared with many other species of mammals and birds, diet analysis for carnivores is relatively easy, although it has some serious problems. Food usually consists of clearly discrete items, which can be recognized and quantified. Furthermore, scats are often easy to find, no matter how elusive the animals may be, and scat analysis has become a major tool despite the difficulty of relating scat content to diet in a quantitative manner. Also, for many species it has proved possible to obtain direct, quantitative observations of predation and foraging behavior. The result is an extensive body of knowledge of carnivore diet, the important link in the relation between the predators and their environment.

One summary showed that of 111 species of carnivore (from all families), only 36% could be classified as predominantly meat eaters, i.e., taking more than 60% of their diet in the form of other mammals or birds. Indeed, in that analysis among representatives of families such as the bears, raccoons, and viverrids, there were no proper meat eaters at all, and they were found to feed on insects, vegetation, or a mixture of various food categories. Many species were called omnivorous if their diet did not include 60% of any one category of food. However, such a limit is quite arbitrary, and many important species were left out of the analysis because of lack of information. Therefore, it is an oversimplification, and one could also summarize the diet differently (Figure 4): The majority of carnivore species will eat meat and will prey on other mammals at some time or other. However, the point had to be made that many other kinds of food are involved.

There is a clear importance of phylogeny in the diet: The food of a felid tends to be more like that of another felid than that of a canid and vice versa, and this applies to several families (Figure 4). All families except the felids are intensive exploiters of vegetable and invertebrate food sources: The Felidae are the most exclusively carnivorous—the ultimate predators. Only the felids, hyaenids, and canids

feed significantly on large mammals, with an occasional exception in the other families. The viverrids, which are probable ancestors of felids and hyaenids, do not kill larger mammalian prey but they are either insectivorous or have a very mixed diet. The diets of the four hyenas are more different from each other than between the members of the other families, and their specializations range from wildebeest to termites or melons or carrion. The bears and pandas are vegetarians. Species in the raccoon family all have a mixed diet, including much vegetable matter. Canids have mostly varied diets, composed of insects, fruits, and mammals. Many of them are proper meat eaters, but even these often include some vegetable matter, quite unlike the cats.

Some of these family-specific trends are further refined in the subfamilies. The mostly meat-hunting mustelids also include two subfamilies with 9 badgers, which almost all feed on invertebrates and vegetation, and a subfamily of 13 otters that subsist on fish or crabs.

Not only are there differences between families and subfamilies in the kinds of prey or vegetation which they select, but also the degree of specialization varies (Figure 5). Specialization can affect an animal's vulnerability to environmental change. Among the canids, each species uses an average of 6.5 (out of 10) major prey categories, each constituting at least 1% of its food. On the other end of the scale, each bear only uses 3.7 prey categories and each felid 4.0, so they are much more specialized. The other carnivore families are intermediate. This specialization (dependence on a few resources) may make bears and felids more vulnerable to environmental change than canids.

The degree of specialization can be described only in the broadest of terms because it is difficult to measure and quantify. Terms such as omnivore, opportunist, generalist and specialist have no absolute values, and they refer to animals which may be selecting from a variable set of availabilities. There is also a problem with definitions. For instance, the Eurasian badger is highly focused in its food selection in any one area, concentrating entirely on earthworms in northwestern Europe, on rabbits in southern Spain, and on olives in northern Italy. There is no doubt that in each of these areas badgers are highly specialized, but their specializations are different in different places and overall they could be described as opportunists. Currently, there is no good quantitative descriptive term for such a pattern.

Nevertheless, despite inadequate terminology it is recognized that in any one place some species use many more different prey categories than others. For instance, a cheetah on an African savanna takes almost only small or medium-sized ungulates on open grassland, whereas a leopard in the same area is much more catholic in its tastes. It eats the same mammals but also much smaller mammals as well as birds and snakes, stalking them in the open and in dense bush or between the rocks. Along European streams a mink will eat small mammals, frogs, fish, birds, and insects, whereas along the same banks the (larger) otters feed almost exclusively on fish and frogs, clearly much more focused. Such a broad comparative indication of specialization suggests the dependence of a predator on few or many prey categories, even

Figure 4 The use of different foods by species from different families. Percentage of species in each family in which a particular food category constitutes more than 1% of diet. Veg, vegetable foods; inv, invertebrates; amp, amphibia and reptiles; rod, small rodents; lag, rabbits and similar size prey; s.mam, large mammals smaller than 50 kg; l.mam, large mammals larger than 50 kg; car, carrion. Reproduced from Kruuk H (1986) Interactions between Felidae and their prey species: A review. In: Miller SD and Everell DD (eds.) *Cats of the World: Biology, Conservation and Management*, pp. 353–373. Washington, D.C.: National Wildlife Federation.

though there may be difficulties with labeling as specialist or opportunist.

In general, because closely related animals often have similar food habits, food selection may be termed a conservative characteristic in the evolution of carnivores. There are many exceptions; for instance, among the meat-hunting felids there is a fishing cat, and the hyena family includes the aardwolf, which feeds on nothing but termites, the spotted hyena, which is an exclusive large ungulate hunter or scavenger, and the striped and brown hyenas, which are as catholic in their tastes as possible. However, these exceptions do not invalidate the overall importance of ancestry in the animals' environmental relationships.

Carnivore Guilds in Ecosystems

Closely related members of the same carnivore family tend to exclude each other, although there are important and puzzling exceptions. Of course, competition between natural populations of different carnivores is rarely observed, probably because those cases in which it occurred have long ago come to their natural conclusion, i.e., the demise of one of the contestants. However, when perturbations occur competition may be obvious. For instance, the introduction of the American mink in Europe totally removed the European mink from most of its range. The famous wolf population of Isle Royal arrived there in the early 1950s, and it completely replaced a

Figure 5 The number of food categories used by species of different carnivore families. *N*, number of species studied, with mean and standard deviation of the number of major food categories (see also **Figure 4**). Reproduced from Kruuk H (1986) Interactions between Felidae and their prey species: A review. population of coyotes. There are several observations of wolves killing coyotes, apparently without the coyotes being eaten. In many other areas in North America, just one of the two species is found, although usually these places would appear to be suitable for both. Coyotes tend to replace red foxes.

Red foxes are aggressive to arctic foxes and exclude them when their areas overlap, but arctic foxes can feed and survive at much lower temperatures. Recent red fox increases (e.g., in northern Scandinavia) caused the demise of arctics over large areas. In the 1970s, when the black-backed jackals of the Serengeti were decimated by disease, the very similar and previously rare side-striped jackal population increased dramatically. Tigers are reported to often exclude leopards, and different species of otters exclude each other.

Also, species that are not closely related but have overlapping ecological niches may affect each other. For instance, the African wild dog disappeared from the Serengeti between the 1960s and 1990s probably partly because of an increase in populations of hyenas and lions.

Exceptions to this pattern of exclusions are the three species of African jackal. They are very similar and closely related; nevertheless, their geographical ranges overlap considerably and they can be seen eating from the same carcass.

There are other examples of perturbations or species introductions causing the disappearance of competing carnivores, but such events are relatively rare. Thus, it is often assumed that populations of predators each have their own ecological niche and rarely affect each other. However, the ecosystems that we see are end results, and often what we see may be the status quo long after earlier populations

have been wiped out or have been prevented from moving in.

One way in which predator species adapt to an ecological niche in a particular habitat is through morphological or behavioral variation. When potentially competing species share a range, differences between them (e.g., in size) may be greater than those from animals that live in ranges not shared with the other species. This is known as character displacement. One of its consequences is that in a guild of predators in any one area a character, such as body size or size of the canines, shows a fairly evenly spaced stepwise distribution among species (**Figure 6**). The obvious effect of this is to minimize competition. Such divergence of morphological characters does not always occur, however, and its striking demonstration in British mustelids is contrasted with an almost absence in Serengeti jackals. The marsupial carnivores of Tasmania also show a clear character divergence.

The existence of such structured mechanisms, to avoid competition within predator guilds in ecosystems, suggests that resources for the carnivores may be at a premium. This in turn presents the possibility that the predators depress prey populations.

It is often argued that predators have little or no effect on prey numbers, as demonstrated by ecosystems such as the Serengeti with more than 25 carnivore species that coexist with the many prey in apparently stable populations. However, such an apparent stability is the result of interactions over a long period of time, and it is possible that many prey species were extinguished in the past and many predator-prey relationships have not had a chance to become established (as first arrivals in the ecosystems were eliminated).

Figure 6 Even spacing of mean lengths of skulls of Mustelid species in Britain and Ireland, log scale. The mink has recently been introduced. Reproduced from Dayan T and Simberloff D (1994) Character displacement, sexual dimorphism, and morphological variation among British and Irish mustelids. *Ecology* 75: 1063–1073.

The deliberate or accidental introduction of carnivores into ecosystems in which they were previously absent provides an opportunity to demonstrate effects of predation. Introduced predators (cat, dog, red fox, mongoose, American mink, stoat, and ferret) have caused extinctions and declines of endemic prey species throughout the world, including many birds, mammals, and reptiles. There is little doubt, therefore, that carnivores cause extinctions or prevent populations from becoming established, and they must have done so in the evolutionary past. On all continents the fauna would look very different from what it is now if there had been no carnivore predators.

Also in the predator–prey systems which currently exist, the effects of carnivore predation can be far-reaching. Predator removal often dramatically increases numbers in prey populations compared with those in suitable control sites, as demonstrated by foxes preying on partridges. Pest species such as rabbits can be limited in numbers by carnivores operating in conjunction with other mechanisms such as disease. Wolves may exercise major effects on populations of caribou, moose, and white-tailed deer, and spotted hyenas can have a major effect on wildebeest. Often, other limiting factors are involved simultaneously, e.g., predators may be the means whereby a herbivore population is maintained at the carrying capacity of the vegetation.

Carnivore Social Systems

The majority of carnivores are solitary and territorial. Their spatial organization is maintained by females (with or without offspring) defending a range against other females of the same species, and by males defending a (larger) range against other males. Male ranges may overlap with several females ranges. Territorial behavior involves scent marking and visual displays as well as direct aggression.

There are some important variations to this generalization. The marsupial carnivores are not territorial; therefore, instead of a regular spacing between individuals, they are more or less randomly distributed. This begs the question, not satisfactorily answered to date, why eutherian carnivores spend so much

time and effort on risky territorial behavior if other species with similar ecology can do without.

The organization of canids is pair based rather than solitary; a male and a female share the same range. This is also the only family in which males usually assist in providing the offspring (by regurgitating food). The fact that such pair behavior is tied with the species' phylogeny suggests that in individual species it is not necessarily adaptive.

From the simple, territorial arrangement a group organization has evolved independently in several species in all carnivore families except the bears, and such group living has complicated land tenure considerably. Among the canids the most striking examples are the wolf, the wild dog, and the dhole in Asia, but in several other canid species offspring may also remain for 1 or 2 years, overlapping in time with subsequent litters of the basic pair. This has been described for several jackals, foxes and others.

African wild dogs live in extremely tight packs, often composed of 20 or more individuals, almost always close together, with on average twice as many adult males as females. The wolf has a very different organization. It also lives in sometimes large packs, but it does so in a much more "fission–fusion" type of society, with individuals coming and going, sometimes hunting in groups and sometimes alone, within the pack territory. In both species usually only one female per pack breeds.

Group organizations in other carnivore families show as many different patterns as there are species, with, for instance, lions in permanent prides of up to 20 related females joined by small groups of males which are replaced every few years. Spotted hyenas live in female-dominated clans of up to 80 in group territories, and individual members may hunt or join with others or they may be solitary within the group territory. Cubs are cared for almost entirely by their own mothers. Both banded and dwarf mongooses occur in dense packs, with the sexes mixed, and all members of the pack care for all offspring. Eurasian badgers forage on their own and look after their own cubs only, but they live in group territories defended by both sexes. Female Eurasian otters, on the other hand, may occupy individual core areas within a group territory of five or six females, whereas males remain in their own ranges.

For the phenomenon of group living in carnivores, there are no striking, simple phylogenetic trends and no substantial effects of body size, climate, prey size, predation, or various other factors to explain the occurrence of packs, bands, or prides. It does not appear that social species have done any better or worse than solitary ones in terms of numbers or densities, nor is their future survival more or less endangered. There is, however, one set of environmental factors which appear to affect gregariousness, i.e., the distribution of food or of resources in general.

Currently, there is only one general hypothesis to explain grouping of carnivores—the resource dispersion hypothesis, first explicitly presented by Macdonald (1983). In principle, it relates the size of territories and the numbers of animals inhabiting each territory to the spatial and temporal pattern of resources. For instance, it suggests that badgers in northwestern Europe live in groups because their main food, earthworms, occurs in well-spaced patches, each of which is available only at certain times. To be able to feed at all times a badger needs a large area with several patches, with the size of the area determined by the scatter of the patches. Once a badger has such a territory it can accommodate several more individuals with only limited or no competition. The hypothesis is attractive, but it does not explain all the intricacies of spatial organization. To date, there is no comprehensive alternative.

Carnivores living in groups may or may not hunt cooperatively, depending on species or conditions. Clear advantages of cooperation, in terms of hunting success or energy balance, have been demonstrated for wild dogs and spotted hyenas. Lions collaborate on a well-organized basis, with each pride member occupying a preferred place in the hunting formation and deviations of this pattern resulting in lowered success.

Changes in Diversity

When the Carnivora first appeared, approximately 60–40 million years ago, there were other, similar animals already well established. For instance, the extinct order Creodonta included families such as the Hyaenodontidae, and there were various large marsupial predators such as the Thylacoleo or pouch lion. Proper carnivorous feeding and predation have evolved several times independently—at least twice among the marsupials (in the Borhyaenidae in South America and some Dasyuridae in Australia) and twice among placental mammals (in Creodonta and Carnivora).

The large carnivorous expansion from the Palaeocene onwards coincided with the evolution of angiosperms, flowering plants and grasses (evolving away from the ferns and gymnosperms such as conifers). This resulted in a large floral diversification, including savanna-type vegetations, and enabled the extensive diversity of ungulates and rodents to evolve. This in turn enabled the evolution of specialist predators.

Most of the other, noncarnivore large predators have now gone extinct, with the last creodonts occurring approximately 8 million years ago and the last really large marsupial carnivores occurring 2 million years ago, when species of *Homo* were already well established. Of the smaller marsupial carnivores, just a few small dasyurids still occur in Australia.

However, while the other predators slowly disappeared, the order Carnivora diversified into a multitude of different families, genera, and species.

Why the creodonts disappeared, while at least initially carnivores thrived and probably replaced the creodonts, is a mystery. Creodonts and carnivores were closely related and the skeletal remains, such as vertebrae and the locomotory system, were similar. The difference between creodonts and carnivores was not much greater than the variation within these groups. However, obviously there is more to an animal than its skeleton, and the reasons for extinction may well have lain in other aspects of morphology, physiology, or behavior.

In the early stages of evolution the advantages appear to have lain with the creodonts, and only after 20 million years did the balance tip in favor of the Carnivora. The Carnivora have been four times as successful as the creodonts: The latter are known from 45 genera spanning approximately 45 million years, whereas Carnivora, excluding living and aquatic genera, are known from 218 genera over a span of more than 55 million years.

Carnivore species are also fewer now than they were in the geological past. In fact, most of the Carnivora have become extinct, and although there is still a rich complement of species, there were many more in the past. For instance, we know of 333 genera in the seven extant families of carnivores, of which 237 (71%) are extinct. Many complete carnivore families have also disappeared, just like the creodonts and large marsupial predators.

An interesting phenomenon was the occurrence of saber-tooth species. Saber teeth evolved several times independently in different species, families, and even orders and included the Megantereon, Homotherium, and Machairodus, which were at least as big as a lion, and formidable felids such as the North American saber-tooth cat *Smilodon*. Some of these were present at the same time as early species of *Homo*, but all of them are extinct. They pose a difficult problem to paleontologists. Large canines are used by today's carnivores for killing prey and for social purposes such as fighting opponents over territorial claims. However, were the extra-large saber teeth—the huge, flat daggers which were seemingly far too large for any jaw—used to kill extra-large prey, for opening carcasses, or what? In fossil assemblages it was always the very largest ones, the top predators, which sported saber teeth.

There is no likely explanation for saber teeth in the acquisition of food. The fragile, sharp weapons, often with serrated inner edges, must have been quite useless against thick skin or on large bodies, with the gape of the owner being insufficient to use these canines effectively. However, saber teeth were obviously effective weapons; otherwise, they would not have evolved several times independently. However, they also disappeared again in all these cases. It is likely that saber teeth made use of some Achilles heel in their prey (of which we have no evidence today), but that in response the prey species evolved means of protection. It was an arms race which was eventually lost by the sabers, but we do not know who conquered and why.

Homo is a highly successful hunter, and mankind was and is in competition with Carnivora at several different levels. *Homo* also preys on and is preyed on by Carnivora. Therefore, are people the cause of carnivore extinctions? The question is

often asked, and answers are far from straightforward. Many carnivore species extinctions occurred approximately 4 million years ago, at the time that hominids arrived on the scene, and many followed during the next 2 million years.

However, many extinctions occurred before man arrived, and at the time *Homo*'s arrival was not the only event which changed the environment. There were drastic changes in climate, for instance, approximately 3.2, 2.4, and 0.8 million years ago. The Pleistocene Period started at 0.8 million years ago with a massive climatic shift that coincided with the appearance in Eurasia of African species such as the lion, leopard, spotted hyena, and perhaps the major (although not the first) movement out of Africa of *Homo*. If such major dispersal events occurred in conjunction with climatic changes, it is equally likely that extinctions would have occurred.

For many of the carnivore extinctions, we cannot blame our own species with any conviction. *Homo* may have been closely involved or not at all, and perhaps environmental change rendered species more vulnerable to competition and predation by mankind. Of course, recent extinctions have been fairly well documented, and here mankind's guilt is in no doubt. The Tasmanian wolf or *Thylacine* was exterminated by sheep farmers in the 1920s and 1930s. The North American sea mink was obliterated in the late nineteenth century for its fur, and the sea otter almost followed it into oblivion; it was barely saved and it has recovered fairly well. The "wolf" of the Falkland Islands was still there when Charles Darwin visited, but sheep farmers exterminated it and since the 1880s it has existed only in museums. Several carnivores were totally eradicated from Britain, including the brown bear and the wolf, whereas wildcat, polecat, and pine marten have only just managed to survive. There are long lists of carnivore extinctions from throughout the world, and there is no doubt that most of these were man induced.

Whatever caused the demise of carnivore species in the past, it is important to prevent it from occurring in the future.

Several species are on the brink of extinction in the wild, including tiger, panda, European mink, and black-footed ferret, and many more face local extermination. In geological terms, the diversity of carnivores is decreasing extremely rapidly.

Glossary

Adaptive radiation The evolution of ecological and phenotypic diversity within a rapidly multiplying lineage.

Ecoregion A large unit of land or water containing a distinct assemblage of natural communities and species.

Endemic Any taxon (e.g., species, genus, family, order) confined to a particular region.

GABI The Great American Biotic Interchange was the major exchange of land mammals between South and North America after the formation of the Isthmus of Panama, about 2.7 million years ago.

Rapoport effect A pattern where the size of a species' geographic range increases toward higher latitudes.

Introduction

The characteristics and biogeography of Neotropical mammals have been the focus of copious literature. The interest in the Neotropical region lies in its long isolation during the Cenozoic Era (Age of Mammals), particularly in South America, and the extensive radiations that led to a remarkable fauna within a context of heterogeneous topography and extraordinary diversity of ecoregions. The foundations of the knowledge of Neotropical mammals were laid in the voyages of Christopher Columbus in 1492, naturalist expeditions up into the nineteenth century, as well as by pioneers of South American mammal paleontology (Hershkovitz, 1987).

Neotropical Land Mammals: History of Place and Lineages

Among the most prominent contributions to Neotropical mammal biogeography are the studies of Simpson (1950, 1980), Hershkovitz (1958, 1972), Cabrera and Yepes (1960), Patterson and Pascual (1972), Reig (1981), Webb and Marshall (1982) and Mares and Genoways (1982), among others.

The evolutionary history of Neotropical mammals (that is, the history of lineages) should be framed within the dynamic history of place (i.e., changes in geography, geology, climate, and environmental characteristics; Lomolino *et al.*, 2010). Thus, major paleogeographic events were the Division of Pangea into Gondwana and Laurasia, the breakup of Gondwana (into South America and Africa) during the upper Cretaceous, the isolation of South America as an "island continent" for more than 100 million years, throughout much of the Tertiary, the emergence of the Panamanian land bridge, and the rise of the Andean Cordillera.

Chronologically, the immigration of recent land mammals into the Neotropical Region can be divided into three distinct faunal strata (Simpson, 1980; Webb and Marshall, 1981) reflecting older and younger faunal contingents. These strata are the result of a fragmentary fossil record, and represent only a general heuristic framework synthesizing the history of the Neotropical mammal fauna (Figure 1).

Prior to the first stratum, a protohorofauna (i.e., a Mesozoic Gondwanian fauna made up of mammal-like reptiles and true mammals from which part of the following fauna might have

taken their origin; Reig, 1981) was present or had evolved in South America from Western Gondwanian or Laurasian groups; some Neotropical lineages of Stratum 1 may have originated from them (Reig, 1981). Stratum 1 is made up of the ancient autochthonous fauna of the early Cenozoic, and includes the living armadillos, giant anteater, marsupials, and various diverse and now-extinct groups of autochthonous ungulates. Stratum 2 represents the allochthonous lineages present in early Oligocene that includes the caviomorph rodents and primates (the origin of both groups are contentious, but they are probably African). The Stratum 3 corresponds to the young taxa, associated with the emergence of the Panamanian land bridge, and consequently, the large-scale experiment of faunal interchange known as the Great America Biotic Interchange (GABI), during late Pliocene, at about 3 million years ago. Among the mammal invaders from the North American stock are the procyonids (coati and racoon), vespertilionid and molossid bats, skunks, peccaries, cricetid rodents, mastodons, camelids, tapirs, bears, horses, deer, dogs, weasels, cats, leporids and squirrels (Marshall, 1988).

There is still debate regarding these phases, specifically the time and place of entry of some lineages. An example is the long-standing debate regarding the arrival and diversification of the cricetid field mice in South America, particularly the diverse subfamily sigmodontine with more than 300 species. Although there is a general consensus on North America as the place of origin of this lineage, there is controversy on whether their explosive diversification took place in North or South America. Some authors suggest that it occurred in Central America, and that the subfamily was already taxonomically diverse when they arrived in South America, whereas others suggest that the subfamily underwent a large scale adaptive radiation once in South America. The centers of diversity are now in South America, although many species are distributed into Central America and a few in the southern USA (Marshall, 1988; Steppan, 1996).

The Great American Interchange

The most impressive change in the composition of the South American land mammal fauna began in the late Miocene (Webb and Marshall, 1982). During this period, representation of genera from Stratum 1 (autochthonous ungulates and large herbivorous xenarthrans) declined from 70% to less than 20%.

Figure 1 Cenozoic South American land mammal ages and faunal strata.

Concurrently, caviomorph rodents (making up much of Stratum 2) experienced remarkable adaptive radiation into the newly vacant herbivorous niches, ecologically equivalent to mammal groups in other continents (Mares and Ojeda, 1982).

However, the most remarkable episode involved the increase in the diversity of Stratum 3 fauna from 0% to more than 50% of the total genera. At least half of the recent land mammal genera of South America belong to this stratum.

The geological events that took place about 3 million years ago (e.g., tectonic changes and a decrease in sea level) gave rise to the Isthmus of Panama, triggering the GABI. The arrival of the species from Stratum 3 to South America, and a reciprocal faunal interchange with North America, is partly linked to this event. However, some of the mammals of Stratum 3 entered South America before the emergence of the land bridge. During the late Miocene and early Pliocene, island archipelagos may have facilitated waif dispersal (i.e., dispersal across water barriers by island-hopping) across what is now Central America. At the beginning of the Cenozoic, Central America was probably the source area of ancient lineages of marsupials, xenarthrans, and ungulates that dispersed to South America as waif immigrants across the water barrier (Patterson and Pascual, 1972). A successful group that probably arrived as island hoppers in the late Miocene are the sigmodontine rodents (Hershkovitz, 1972; Reig, 1981). At the same time (7–9 million years ago), South American ground sloths entered North America. A summary of the reciprocal land mammal interchange between North and South America is portrayed in Figure 2.

A mass extinction, particularly megaherbivores, affected the Neotropical faunal assemblages at the end of the Pleistocene (Martin, 1967; Marshall, 1988). This coincided with the entrance of humans from Asia into North America across the Beringian land bridge at the end of the last glaciation and continued to South America. Earliest human settlements in South America may date back 14,220 years (Dillehay *et al.*, 2008). In the case of North America, there were about 34 extinct genera, whereas in South America the loss of megafauna (i.e., more than 44 kg) reached 52 genera including mastodons, ground sloths, glyptodonts, and the diverse group of native ungulates (Barnosky and Lindsey, 2010).

The megafaunal extinction during the Quaternary period (Late Pleistocene–Holocene) is hypothesized to be the result of synergistic interactions of environmental modifications and hunting, associated with climate change and the dispersal of early humans into the Americas. Although there has been improvement in the dating of extinctions and paleoclimatic reconstruction, the association of human artifacts and megafaunal extinctions are still a matter of active debate (Barnosky and Lindsey, 2010).

The Zoogeographic Region and their Mammals

Biogeographical Limits and Transition Zones

Hershkovitz (1958) defined a zoogeographic region as

A zoogeographic area, whether Realm, Region, or subdivision thereof, regarded as a faunal district of the earth at a stated time in geologic history. The fauna of a zoogeographic area includes all animals inhabiting that area at the same time irrespective of their place of origin. A zoogeographic boundary between faunal areas is the barrier that prevents a natural and continuous faunal flow from one area to the other. A zoogeographic transition zone is an area on either or both sides of the arbitrarily drawn boundary line between contiguous and contemporaneous faunal areas. Its entire fauna is derived from neighboring areas (1958, p. 584).

Figure 2 The Great American Biotic Interchange and the Central America filter effect. The expansion and retreat of glaciers affected the ecosystem dynamics in Middle America and acted as a filter for the dispersal of certain mammal groups. During the advance of glaciers there was an expansion of the savanna habitats which favored reciprocal dispersal of certain types of fauna to pass through the Isthmus of Panama, whereas during glacier retreats there was an advance of tropical habitats, a contraction of the savanna corridor and consequently a restriction to the dispersal of the savanna faunal groups.

The Neotropical Region was defined by Sclater and Wallace as one of the six major zoogeographical divisions of earth based on their vertebrate assemblages (Sclater, 1858; Wallace, 1876). The region extends from Central America to the southern tip of South America, including continental and oceanic islands, the Bahamas, West Indies, Galapagos, and Malvinas (Falklands). It is subdivided into hierarchically lower divisions known as the West Indian, Brazilian, and Patagonian Subregions.

The delimitation between the Nearctic and the West Indian Subregion is an imaginary line across the Gulf of Mexico and the strait of Florida. The West Indian Subregion consists of a chain of islands including the Bahamas, Cuba, and the Grenadines. The Brazilian Subregion extends from Central America and northern South America up to northeastern Argentina. Major topographic features include the Andes extending along the western portion of South America and the Guianian and Brazilian highlands in the northeast and southeast, respectively. Included in its diverse vegetation are rainforests, savannas, mountain meadows, deciduous and evergreen broad-leave forests, and coastal mangroves. The Patagonian Subregion includes Uruguay, most of Argentina (including Malvinas islands), Chile, the highlands of Bolivia and Peru, and the paramos of Ecuador up to the equator. Major topographic and vegetation features include the Pacific coastal desert, the Andes, the vast Patagonian steppe desert, *Nothofagus* beech forests, arid, and semiarid scrublands, savanna and open thornscrub forests, and grassland habitats (Hershkovitz, 1974).

There have been various different biogeographical approaches and methodologies to set the boundaries between the Nearctic and Neotropical zoogeographic regions. Some of these proposed limits based on the southern and northern geographic range edges of mammals are synthesized in the inset of Figure 3. Disagreement among these regions are due to different methodologies and taxa analyzed. Thus, the boundary between the Nearctic and Neotropical Regions based on the distributional patterns for different taxonomic levels (i.e., families, genera, and species) shows that the southern boundaries of Nearctic taxa are located in northern Mexico up to the Mexican Plateau (Escalante *et al.*, 2010). Another quantitative analysis of the distribution of bats in Mexico and Central America (i.e., cells of presence/absence occupancy) found a similar pattern for the southern limits of the Nearctic region, with minor differences regarding the extent of the transitional zone (Ortega and Arita, 1998).

The boundaries between biogeographic divisions (referred to as transition zones especially on land), are difficult to determine and are unrealistically portrayed as sharp lines. Instead, these boundaries represent dynamic areas of biotic overlap, active belts of intense faunistic interactions and large-scale population dynamics (Ortega and Arita, 1998; Escalante *et al.*, 2010; Morrone, 2009; Lomolino *et al.*, 2010).

The transition zone between the Brazilian and Patagonian Subregions runs diagonally between southern Ecuador, Peru, Bolivia, and southeastern Brazil, and into Argentina. In

Figure 3 The Neotropical Region and subregions (adapted from Hershkovitz, 1972). The insert map depicts several delimitations of the Neartic-Neotropical transition zone that were proposed by different authors.

northwestern Argentina, the Brazilian Subregion extends like a peninsula (see [Figure 3](#)) including the southernmost montane cloud forests which stretch to northern South America along the eastern flank of the Andes (Tropical Andes hotspot). Mammal distributions in this transition zone result in a broader transitional area which is roughly congruous with previous boundaries established by Sclater and Wallace as well as the “subtropical line” of [Ruggiero et al. \(1998\)](#).

Diversity and Classification of Mammal Groups

The geological history and biotic diversity of the Neotropical Region are the focus of active research, with active discovery of new taxa at various levels. Extant Neotropical mammals represent one quarter of the world's mammal fauna. Eight of the

20 richest countries in mammals are in the Neotropical Region (Brazil, Mexico, Peru, Colombia, Argentina, Ecuador, Bolivia, and Venezuela, in descending order). However, tabulations of mammal species are imprecise, with new species (particularly marsupials, insectivores, primates, bats, and rodents) being discovered and described rapidly ([Patterson, 1994, 2000](#)). New mammal discoveries are particularly significant in South America, especially in areas of high endemism such as tropical biomes (e.g., Central America, eastern tropical Andes, the Amazon basin, and Atlantic forests), and temperate semiarid habitats.

On average, 223 new mammal species are described every 10 years. Of the 62% newly-described New World mammal species in recent years, 93% were from the Neotropical region,

mostly from the tropical and semitropical regions of Mexico and Brazil, the Andes of Colombia, Peru and Ecuador, as well as the temperate areas of Chile and Argentina (Ceballos and Ehrlich, 2009; Reeder *et al.*, 2007).

Of the about 1550 mammal species recently estimated for the Neotropical Region (Solari *et al.*, 2012), 1421 species are from land habitats, and 946 of these (66%) are endemic.

The Neotropical Region has the highest diversity of mammals in the New World, with 15 orders of terrestrial and marine mammals three of which are endemic. The marsupials belonging to the orders Microbiotheria (e.g., monito del monte) and Paucituberculata (i.e., rat and shrew opossums) are mostly restricted to the Patagonian Subregion, whereas the order Pilosa (giant and lesser anteater, and two and three-toed sloths) is restricted to the Brazilian Subregion.

With respect to families, the Neotropical Region has the largest number of endemic families of terrestrial mammals, 29/56. The endemism ratio (endemic families/number of families) of other biogeographic regions is: Palearctic: 1/36; Neartic: 2/31; Afrotropic: 20/58; Indo-Malayan: 8/49, and Australasian: 21/35 (Vaughan *et al.*, 2011).

A General Account of the Neotropical Mammal Fauna

This section provides an overview of the Neotropical mammals. Figure 4 depicts some representatives of these orders and endemic families.

Didelphimorphia – This is an ancient lineage of small to medium-sized marsupials in the Neotropical Region. They occupy a wide diversity of habitats and macroniches (arboreal, scansorial, and semiaquatic; insectivores, frugivores, omnivores, and carnivores). Some genera are *Didelphis*, *Caluromys*, *Glironia*, *Lutreolina*, *Phyllander*, *Thylamys*, and *Monodelphis*. All species are endemic to the Neotropical Region, except for the common opossum, *Didelphis virginiana*, which extends its geographic range into the Neartic Region up to Canada.

Paucituberculata – This endemic order of small insectivorous marsupials is confined to South America and is represented by a single family containing the genus *Caenolestes*, *Lestoros*, and *Ryncholestes*. Their distribution extends across Ecuador, Peru, and Bolivia (*Caenolestes*, *Lestoros*), and southern Chile (*Ryncholestes*).

Microbiotheria – This is a monospecific order with a single family and species, endemic to South America, the small marsupial *Dromiciops australis*. (“monito del monte”). It feeds on larvae, insects, and fruits, and is restricted to the Valdivian temperate rainforest of *Nothofagus* in Argentina and Chile. Phylogenetically, it is more closely related to Australian marsupials than to South American ones.

Sirenia – This group is represented by the family Trichechidae, and composed of three species which are endemic to the Amazon and Orinoco basin of the Brazilian Subregion. They are strictly aquatic and herbivorous, and include the manatee (*Trichechus*) and Amazon river dolphins (*Sotalia*, *Inia*).

Cingulata – This order, along with Pilosa and the marsupials, are among the emblematic “old inhabitants” of the Neotropical region. The order Cingulata includes a diverse suite of armadillos with varying body sizes, ranging from the pink fairy armadillo (100 g) to the giant armadillo (30 kg). Representative genera are: *Dasyus*, *Euphractus*, *Cabassous*, *Priodontes*, *Tolypeutes*, *Chaetophractus*, *Chlamyphorus*, *Calyptophractus*

and *Zaedyus*. Armadillos do not occur in the Neartic Region (North America) with the single exception of *Dasyus novemcinctus*, which extends into southeastern United States. They are omnivores that feed on insects, larvae, eggs and fruits.

Pilosa (=Edentata) – This order includes the tree sloths of the genus *Bradypus* and *Choloepus*, and the anteaters (*Tamandua*, *Myrmecophaga*, and *Cyclopes*). Tree sloths are arboreal folivores, feeding on leaves and buds; they are mostly tropical in their distribution, and occur from Central America to near the Tropic of Capricorn in northern Argentina. Anteaters are terrestrial and semiarboreal and feed on ants and termites.

Primates – Primates are represented by two endemic and one cosmopolitan (Hominidae) families which includes humans, *Homo sapiens*. Neotropical monkeys are mostly tropical forest species and are small to medium size. Among them, the pigmy marmoset, *Cebuella pygmaea* with a body weight of 70 g, is the smallest of the living primates. Neotropical monkeys are arboreal and with a diet of insects, leaves, and fruits. Whether they originated in Africa or Asia is still a matter of debate. Representative genera, many of them highly endangered, include *Cebuella*, *Saguinus*, *Callithrix*, *Leontopithecus*, *Aotus*, *Saimiri*, *Ateles*, *Alouatta*, *Cebus*, among others.

Rodentia – Rodents are represented by four major groups, or suborders: Sciuromorpha, Castorimorpha, Hystricomorpha, and Myomorpha. Of these, the Castorimorpha and Sciuromorpha are of northern origin, and they reach their southern distributional limits in distribution in northern South America and near the Tropic of Capricorn, respectively. Representative genera of Sciuromorpha are squirrels, *Sciurus*, whereas the Castorimorpha is represented by subterranean pocket gophers (*Geomys*, *Orthogeomys*) and spiny pocket mice (*Liomys*, *Heteromys*). The other two suborders, Hystricomorpha and Myomorpha, include the endemic and highly diversified caviomorphs (the South American hystricomorphs) and sigmodontine rodents, respectively, which underwent explosive adaptive radiation in the Neotropics, mainly in South America. These two groups account for more than 550 species, ranging from 12 g to 50 kg (e.g., the largest living rodent, capybara), and occupy a full array of habitats and modes of life. Caviomorph rodents comprise 11 endemic families and some genera are *Galea*, *Dolichotis*, *Abrocoma*, *Ctenomys*, *Octodon*, *Tympanoctomys*, *Spalacopus*, *Proechimys*, *Hydrochaeris*, *Agouti*, *Dasyprocta*, *Cuniculus*, and *Coendu*, among the most conspicuous. Representative genera of sigmodontine rodents are: *Isthmomyss*, *Ichthyomys*, *Oryzomys*, *Thomasomys*, *Wiedomys*, *Calomys*, *Sigmodon*, *Akodon*, *Eligmodontia*, *Phyllotis*, *Salinomys*, *Euneomys*, and *Abrothrix*.

Lagomorpha – This order is represented by the family Leporidae (rabbits and hares) and includes the North American cottontail rabbits. In the Neotropical Region it is represented by the genus *Sylvilagus*. Some of these herbivorous mammals have distributions from Central America to northern Argentina and southern Brazil. Other members of this family are represented by the European rabbit (*Oryctolagus*) and European hare (*Lepus*), introduced by humans in the Neotropical region.

Soricomorpha – This order includes the insectivorous shrews which are distributed across Central America, the West Indian Subregion, and barely into the subtropical Andes in northern South America (genus *Cryptotis*). The endemic family

Solenodontidae includes two endangered species of the genus *Solenodon* distributed in Cuba and the Dominican Republic.

Chiroptera – Bats, the second most speciose mammals in the Neotropical Region. Six out of nine families are endemic

here; their feeding niches are highly diversified and include sanguivores, frugivores, insectivores, carnivores, nectarivores, pollinivores, and piscivores. Representative genera of different families are *Noctilio*, *Glossophaga*, *Brachyphylla*, *Carollia*, *Tonatia*, *Desmodus*, *Vampyrops*, *Artibeus*, *Mormoops*, *Peroptryx*, *Thyroptera*, *Natalus*, *Molossus*, *Lasiurus*, and *Eumops*.

Carnivora – This is a diversified group of mammals occupying terrestrial, arboreal, aquatic and marine habitats. They are represented by eight families which are widely distributed in the Neotropical Region and include the large and medium-size spotted cats, weasels, skunks, river otters, elephant seal, sea lions, foxes, raccoons, coatis, and the spectacled bear. Representative genera are *Panthera*, *Felis*, *Galictis*, *Conepatus*, *Lutra*, *Lontra*, *Nasua*, *Potos*, *Tremarctos*, *Hydrurga*, *Mirounga*, *Arctocephalus*, and *Otaria*.

Perissodactyla – This ungulate group possess an enlarged middle digit on the anterior and posterior limbs, hence the name of odd-toed ungulates. The order is represented by three species of tapirs in the genus *Tapirus*, among the largest terrestrial mammals in the Neotropical Region. They occur from Central Mexico to northern Argentina and feed on grasses and fruits. They are mostly distributed in tropical and gallery forests, forested foothills, tropical Andean paramos, and riverine environments.

Artiodactyla – These are the even-toed ungulates. In the Neotropical Region this order is represented by three families. Representative genera are *Tayassu*, *Lama*, *Vicugna*, *Pudu*, *Mazama* and *Ozotoceros*, and include the peccaries, guanacos, vicuñas, pampas deer and brocket deer, and pygmy pudu deer. Their diet is mostly herbivorous (deer and camels) and omnivorous (peccaries) and they are distributed from southern North America (collared peccaries; genus *Tayassu*) to the southern tip of South America (guanacos).

Cetacea – A group of strictly marine mammals that is distributed worldwide and represented by whales, dolphins, and porpoises; they feed on fish and small crustaceans. Representative genera are *Pontoporia*, *Delphinus*, *Lagenorhynchus*, *Orcinus*, *Tursiops*, *Phocoena*, *Mesoplodon*, *Physeter*, *Balaenoptera*, *Megaptera*, and *Balaena*.

Biogeographical–Macroecological Patterns

Patterns of Species Richness

The distribution and diversity of Neotropical mammals have been analyzed for many groups utilizing different biogeographic approaches, from the continental scale (e.g., Mesoamerica and South America) to regional biomes and countries. The inverse relationship between richness of Neotropical land mammals and latitude is similar to that found for many other taxa of plants and animals. One of the first to quantify and explain this large-scale pattern of decreasing species richness from low equatorial latitudes to high temperate latitudes for the mammals of the Nearctic region (North America) was [Simpson \(1964\)](#). This pattern has been analyzed and corroborated for the New World mammals and several taxa such as marsupials, bats, caviomorph rodents and carnivores, among others. The highest concentration of terrestrial (nonvolant) mammals in South America, is found along the eastern Andes of Bolivia, Peru and Ecuador, the Amazon Basin, and the Atlantic Rainforests of Brazil ([Mares and Ojeda, 1982](#); [Kaufmann, 1995](#); [Ruggiero, 1994](#); [Tognelli and Kelt, 2004](#) ([Figures 5 and 6](#)).

Although researchers agree on the generality of this latitudinal trend, there is considerable debate over its causes (i.e., historical, ecological, climatic stochastic and integrative hypotheses, [Chown et al., 2004](#); [Lomolino et al., 2010](#)). For example, the large area of tropical South America has been suggested to explain diversity of biotas at both continental and island scales ([Mares and Ojeda, 1982](#); [Rosenzweig, 1995](#); [Rosenzweig and Sandlin, 1997](#)). However, the latitudinal diversity gradient for New World marsupials and bats could be explained by a null model (i.e., the pattern in species richness could be a consequence of stochastic mechanisms independent of any particular factor or environmental gradient), up to some extent ([Willig and Lyons, 1998](#)). However, further analysis of the joint effects of latitude and area has shown that latitude is the dominant factor which explains greater than 50% of the variation in mammal species richness. This relationship is independent of area, which contradicts the explanations involving area as one of the major drivers in species diversity ([Kaufmann, 1995](#); [Lyons and Willig, 1999](#)).

Regardless of this debate, global trends of latitudinal diversity in mammals are driven by a combination of factors, including energy availability, topographic complexity, and area, among others. As a result, land mammal species richness peaks toward the equator, in conjunction with primary productivity, whereas richness of marine mammals peaks at approximately 40° N and S, corresponding to belts of high oceanic productivity ([Schipper et al., 2008](#)). In the particular case of South America, energy input converted into larger primary productivity and then translated into greater resources available to consumers, explains a large part of the latitudinal diversity gradient ([Tognelli and Kelt, 2004](#)). Other variables such as habitat heterogeneity, topographic variability, climate, and number of ecosystems, are less important in determining mammalian species richness at this continental scale of analysis, although they are relevant in explaining mammal diversity at regional and local scales. Furthermore, despite corroboration of this relationship, some of the reported differences between results on large scale latitudinal gradients are

Figure 5 Patterns of latitudinal diversity in North and South American mammals.

likely due to the utilization of different databases, methodology, scale of analyses, number and type of taxa involved, and statistical models ([Kaufmann and Willig, 1998](#); [Tognelli and Kelt, 2004](#)).

In general, ongoing research regarding the explanation of latitudinal gradients in species diversity is shifting from the need to find a unique driving factor to a more integrative approach of hypotheses and theories combining several factors ([Lomolino et al., 2010](#)).

Detailed reviews and summaries of current knowledge and compelling hypotheses for a latitudinal gradient in species richness have been provided by [Rosenzweig \(1995\)](#), and [Lomolino et al. \(2010\)](#).

Areographic Patterns and Ecogeographic Rules

Sizes and shapes of geographic ranges are influenced by the topography of the region. Thus, South American mammal geographic ranges become more asymmetrical (relative to a circle) toward the west as a result of the topographical complexity of the Andes. The most widespread species are located in eastern Brazil, whereas the most restricted species are associated with the Andes. The major contrast in South American mammal range sizes therefore occurs in an east – west direction, along the boundaries between the Guayana-Brazilian and Andean-Patagonian Subregions, in accordance with the classical zoogeographical delimitations ([Ruggiero et al., 1998](#)).

The increase in body sizes from the equator toward the Poles (toward high, colder latitudes) is a generalized pattern known as Bergmann's Rule ([Lomolino et al., 2010](#)). However, there is marked contrast between patterns among the mammal faunas of the Nearctic (North America) versus the Neotropical Region. Although in the Nearctic Region body size is negatively correlated with temperature, increasing toward high latitudes, in the Neotropical Region there is a positive correlation with temperature such that mammals are larger in warmer tropical latitudes and smaller in the mountainous Andean regions.

Figure 6 Patterns of diversity of South American nonvolant mammals.

A suggested explanation for this is that reduced habitat in mountains produced an area effect resulting in fewer large-sized mammals (Rodríguez *et al.*, 2008; Ruggiero, 1994).

Another ecogeographic rule known as the Rapoport Rule (Stevens, 1989), states that the latitudinal ranges of species tend to increase toward higher latitudes. An explanation for this trend is that greater climate seasonality and variability at high latitudes exerts a selective effect promoting greater flexibility and larger geographic ranges of species. In South America, Rapoport's rule is consistent with observed patterns only for carnivores and primates; support is less clear for caviomorph rodents, marsupials, and artiodactyls. Anteaters, tree sloths, and armadillos show the opposite trend, with their geographic ranges decreasing toward higher latitudes Ruggiero (1994). Overall, contrary to the Nearctic Region, there is a lack

of evidence regarding increases in geographic ranges toward higher latitudes in South America. This could be associated with the fact that there is less temperature variation in the southern hemisphere, compared to the northern hemisphere (Chown *et al.*, 2004).

Mammal Conservation and Major Threats

As a result of the Neotropic's high mammal diversity and endemism, their conservation is a key issue in the region. Roughly, of the 76 world mammal species that have become extinct in the past 500 years (<http://roboconsumer.wordpress.com/2007/09/23/extinct-mammals/>) 34 (45%) occurred in the Neotropical Region.

One of the first extinct canids was the Malvinas (or Falkland Islands) fox (*Dusycyon australis*), an event already predicted by Darwin (1860) during the voyage of the Beagle

“...As far as I am aware, there is no other instance in any part of the world, of so small a mass of broken land, distant from a continent, possessing so large an aboriginal quadruped peculiar to itself. Their numbers have rapidly decreased; they are already banished from that half of the island which lies to the eastward of the neck of land between St. Salvador Bay and Berkeley Sound. Within a very few years after these islands shall have become regularly settled, in all probability this fox will be classed with the dodo, as an animal which has perished from the face of the earth.” (Charles Darwin, The Voyage of the Beagle, 1860, entry for March 16th, 1834)

Most of these extinctions were the result of a combination of factors, including ecological attributes (i.e., habitat or diet specialists), coupled with restricted insular distributions (e.g., Haiti, Dominican Republic, Cuba, Puerto Rico, and Malvinas), and anthropogenic factors affecting mammals worldwide, such as overhunting, habitat destruction, and the introduction of alien species (e.g., rats, cats, and dogs) (Schipper *et al.*, 2008). In the long term, global climate change is becoming a matter of increasing concern (MacLean and Wilson, 2011).

About 52% of mammals worldwide whose population trends are known, appear to be contracting their geographic ranges and declining their populations (Schipper *et al.*, 2008). At the scale of countries, a detailed overview of the diversity and major conservation problems facing the mammal fauna of the Neotropical Region, such as deforestation, hunting, wildlife trade, and introduction of exotics, was provided by Ceballos and Simonetti (2002). Habitat loss and fragmentation from extensive deforestation is common throughout the Neotropics. In South America, most losses of mammals are associated with cattle grazing and intensive agricultural activities, particularly in the Pampas region (Argentina), Mata Atlantica (Brazil), and coastal areas of Ecuador and Peru. These disturbances are particularly relevant in mammals of temperate South America because of its characteristic high number of endemisms and small geographic ranges (Ceballos and Ehrlich, 2002; Schipper *et al.*, 2008; Lamoreux and Lacher, 2010).

Subsistence hunting, and particularly faunal commercialization, are important threats to mammal populations in the Neotropical Region (Ojeda and Mares, 1982; Iriarte and Jaksic, 1986; Robinson and Redford, 1991) (Table 1). An example of the commercial scale of mammal exploitation is provided by official statistics from the trade of wildlife products (e.g., skins, hides, fur, and meat) from Argentina which represented more than 30 million dollars during 1976–1979 (Ojeda and Mares, 1982). Between 1972 and 1979, Argentina exported 22 million mammals. Despite international agreements on the conservation of marine mammals, the dominant threats are harvesting and accidental mortality, (Schipper *et al.*, 2008).

Biological invasions are another threat to Neotropical biodiversity. An appropriate comment regarding exotic mammals was again made by Charles Darwin (1860) during his crossing of the Pampas and Patagonian landscapes

“few countries [than Argentina] have undergone more remarkable changes since the year 1535, when the first colonist of La Plata

Table 1 Mammal harvesting in the Neotropical Region

<i>Subsistence hunting^a</i>		<i>Commercialization^b</i>
<i>Species</i>	<i>Species</i>	<i>1972–1978</i>
Common Opossum	Nutria	11,011,288
Nine – banded armadillo	Gray Fox	5,789,011
Giant Armadillo	Opposums	1,541,717
Giant Anteater	Skunks	1,243,129
Lesser Anteater	Plains Vizcacha	820,177
Three-toed sloth	Geoffroy's Cat	481,333
Two-toed Sloth	Guanaco	443,655

^bMammal species and number of individuals (skins) exported legally from Argentina during 1972–1978 (data from Ojeda and Mares, 1982).

landed with seventy-two horses. The countless herds of horses, cattle, and sheep, have altered the whole aspect of the vegetation, but they have almost banished the guanaco, deer, and ostrich. Numberless other changes must likewise have taken place; the wild pig in some parts probably replaces the pecari; packs of wild dogs may be heard howling on the wooded banks of the less frequented stream; and the common cat, altered into a large and fierce animal, inhabits rocky hills...” (Charles Darwin, The Voyage of the Beagle, 1860, entry for September 19th, 1833)

The most impacted by invasions are the West Indian and Patagonian Subregions. Exotic mammals in South America represent about 20% of world mammal introductions, but the highest density of exotic mammals is found in the temperate Patagonian Subregion. Most introductions occurred in the eighteenth and nineteenth centuries, with more successful establishment in temperate ecosystems, between 34° and 55° S. They were facilitated by accidental introductions from ships of early explorers, or deliberate introductions in order to establish sport hunting or provide food and fur. Exotic Neotropical mammals include a variety of taxa (e.g., rodents, deer, wild boar, and mustelids), ecological groups (terrestrial and semiaquatic herbivores and carnivores, omnivores). Among the traits that were suggested for the success of invasive species are a high reproductive rate, large size of native geographic range, vacant niches, climatic matching, and so on (Novillo and Ojeda, 2009). Most species are of Eurasian origin and occupy similar ecoregions as in their native areas, although some have expanded their range of habitats. In Cabo de Hornos (55° S), for example, exotic species richness is higher

than that of natives. However, the understanding of the impacts of invasive mammals in the temperate region remains largely anecdotal for many of them (Jaksic *et al.*, 2002; Novillo and Ojeda, 2009).

Approaches and Strategies for Conservation in a Heterogeneous Region

The Neotropical Region includes a diverse and complex mosaic of macrohabitats. **Figure 7** depicts large-scale species richness (=number of species) and level of endemism in South America. Despite the well-known diversity of the Amazon rainforest, the pattern in **Figure 7** highlights the importance of mammal diversity and endemism in non-amazonian dryland biomes (Mares, 1992). One of these is the semiarid thornscrub forests of the Gran Chaco, which covers more than 1 million km² across Paraguay, Bolivia, Argentina,

and Brazil. It possesses a rich fauna of medium- and large-sized mammals equivalent to some of the richest tropical rainforests (Redford *et al.*, 1990). Other important dryland biomes are Mediterranean scrublands, Cerrado, Patagonian steppe, high Andean Altiplano, and Monte desert. Some of these, such as the Mediterranean shrublands and the Chaco, are poorly protected in existing reserves. Further, the plains of the Gran Chaco are currently undergoing a rapid and extensive process of transformation driven by conversion to soybean production (Zak *et al.*, 2008).

Conservation of Neotropical mammals has been approached at various scales and political levels. Scales range from entire assemblages to populations and from major hot-spots (e.g., Mesoamerica) to ecoregions or areas of particular interest (e.g., transitional zones between Neotropical sub-regions). Political approaches have been at the national level

Figure 7 Mammal richness (orders, families, genera, and species) and endemisms in major South American macrohabitats. These macrohabitats differ in size (i.e., area) and the number of species they support is directly related to their area.

down to smaller subdivisions (e.g., provinces). Biodiversity hotspots, i.e., areas which combine extraordinary levels of endemism with low proportions of remaining original habitat, are important in planning and prioritizing mammal conservation at a global scale. The Neotropical Region includes seven hotspots in Central and South America. Among them are the tropical Andes, one of the most diverse regions on Earth. Other hotspots include the Caribbean, which retain 11.3% of their primary vegetation, and the Brazilian Atlantic Forest, with less than 10% of the original habitat. The other hotspots are the Cerrado (the second largest biome in Brazil), the Valdivian temperate rainforests of Chile, and the Tumbes-Chocó-Magdalena wetlands (stretching from Panama to Peru). (Myers *et al.*, 2000; <http://www.biodiversityhotspots.org>).

Despite their potential value, most hotspots are incongruent when considering several biodiversity attributes such as species richness, endemism, and extinction threats. Consequently, there is a need for complementary approaches that incorporate conservation priorities and establishment of reserves and networks.

A useful alternative approach to hotspots is the use of ecoregions. Ecoregion divisions are based on classical biogeography and provide a finer resolution in assessing biodiversity. They can be used as a tool for conservation of species, habitats, and ecological processes of the ecoregion under study (<http://www.worldwildlife.org/science/ecoregions/delineation.html>) (Olson *et al.*, 2001).

At a country scale, reserve networks (i.e., areas representing the total number of species, endemic species, endangered species, and species with restricted distributions) provide contrasts for maintaining regional biodiversity. For example, in megadiverse Mexico, 82% of mammal species are represented in the reserve network, which covers a small portion (3.8%) of the country (Ceballos, 2007). In contrast, in temperate Chile, only a small fraction of the ranges of endemic threatened species are under protection of the reserve system (Cofré and Marquet, 1999; Tognelli *et al.*, 2008).

Prioritizing conservation in areas with high species richness and large numbers of endemic and endangered species is difficult due to the limited geographic overlap in these attributes for any given area. An example of an heterogeneous region is the tropical-temperate transitional belt of the southern cone of South America, where faunal differences in a variety of biomes requires the addition of many complementary reserves to existing ones in order to protect 90% of the total number of mammal species (Ojeda *et al.*, 2003). Overall, regional biogeographic and macroecological analyses of mammal composition, population abundance, degree of occupancy, endemism, and endangerment across the diversity of ecoregions can provide a baseline for additional studies and the establishment of global conservation strategies such as a network of protected areas maximizing complementarity (i.e., protected areas are chosen with the goal of efficiently achieving representation of all species within a particular criteria, such as endemic species, rare species, and so on; Ceballos, 2007).

Prospects

Prospects for understanding the biogeography and conservation of Neotropical mammals are promising. This is not only because of the growing development and quality of

georeferenced databases of mammalian distributions and geographic ranges (e.g., <http://www.natureserve.org/infonatura/>) which help address the Wallacean shortfall (i.e., lack of biogeographic data and its variability), but also because of progress in delineating taxonomic units (Linnean shortfall) and systematic relationships through the advance of genetic and molecular techniques (Lomolino, 2004). Further advances in software applications and sophisticated modeling techniques in spatial analysis of distributions (e.g., GLM, generalized linear models; niche models, as BIOCLIM, GARP, and so on) hold promise of further development for biogeography, conservation, and the macroecology of Neotropical mammals. Together, all of these developments are strengthening the scientific basis of biodiversity conservation and management policies at several geographic scales and political units. However, there is also a need for interdisciplinary *dialog* in order to integrate and build a stronger, more rigorous biogeographical approach, instead of isolated research programs (Brown, 2004). This includes the consolidation of the theoretical foundations of this interdisciplinary science, and making research in this area more useful and relevant to the many problems of rapidly changing human landscapes at a global scale.

The extraordinary biotic diversity and heterogeneous matrix of the Neotropics, one of the most diverse biogeographic regions of the world, is presently experiencing unprecedented threats to major habitats due to a wide array of rapidly expanding human pressures, particularly those associated with commodity production (e.g., impacts of habitat conversion for soybean farming in the Amazon Basin, Cerrado, Chaco, and Pantanal).

A concerted effort among different segments of society is necessary to conserve the enormous mammalian diversity of the region. Unless there is a restructuring process, within the political domain, to equilibrate the disparity among social, environmental, and economic dimensions, the biodiversity losses in the Neotropical Region could escalate rapidly in the near future in the face of rapidly accelerating threats.

Acknowledgments

The author appreciates the invitation extended by Sandra Díaz to participate in the new edition of the Encyclopedia. He appreciates the thorough reviews of Peter Meserve and Marcelo Tognelli, as well as the suggestions on style and editorial improvements of Maria Periago, Mike Wisdom, and Agustina Ojeda. The collaboration of Benjamin Bender with the figures and original illustrations was decisive for the completion of the chapter. He welcomes the support of his institution, the Instituto Argentino de Investigaciones de Zonas Áridas (IADIZA) and the funding agencies CONICET and SECYT to his research program on mammals.

Endangered Amphibians

Tim Halliday, Open University, Milton Keynes, UK

Glossary

Amphibian Member of a class of vertebrates (the Amphibia), comprising frogs and toads (order Anura), newts and salamanders (order Caudata), and caecilians

(order Gymnophiona), which typically return to water to breed and pass through an aquatic larval stage with gills. Amphibians have a moist skin without scales, which is permeable to water and gases.

Amphibians

Amphibians are a group of vertebrate animals that are descended from fishes and which, like fishes, are ectothermic, meaning that the heat that they require to maintain physiological processes is derived externally, directly, or indirectly from the sun. Their dependence on external heat sources limits amphibians to tropical and temperate regions of the Earth and they are especially numerous in the tropics; 80% of the world's amphibian species live in tropical habitats.

Amphibians have a complex life cycle, in which eggs, typically laid in water, hatch into larvae (called tadpoles in frogs and toads), which grow rapidly before undergoing a complex metamorphosis into the adult form. Adult amphibians have a thin, permeable skin that severely limits their ability to retain water within the body. Furthermore, the eggs of amphibians are bounded by only a thin membrane and can only survive if they are kept wet and amphibian larvae are typically aquatic. Consequently, amphibians are restricted, with very few exceptions, to those habitats in which water is available for all or most of the year.

Amphibians are not as well-known, in terms of documentation of species, as either the birds or the mammals. They have been studied less intensively than birds and mammals, are rather secretive in their habits, and are most numerous in parts of the world, notably tropical forests, that have not been fully explored. Consequently, new species of amphibians are being discovered and described at a much higher rate than is the case for birds or mammals. The number of recognized species of amphibians is approximately 6800, but this figure is continuously being revised upward as new species are described.

There are three major groups of amphibians: the frogs and toads (approximately 6000 species), the salamanders and newts (approximately 600 species), and the caecilians (approximately 200 species).

The Conservation Status of Amphibians

Amphibians are threatened worldwide. A recent assessment of the entire group found that nearly one-third (32%) of the world's amphibian species are threatened with extinction, representing 1856 species. Amphibians have existed on Earth for a very long time, about 300 million years, yet over the past few decades nearly 168 species are believed to have gone

extinct and at least 2469 (43%) species are declining in population size, indicating that the number of threatened and extinct species will probably continue to rise. **Table 1** presents the results of the Global Amphibian Assessment, a major international effort to determine the conservation status of most of the world's amphibian species.

Threats to Amphibians

Many environmental factors have been identified that are detrimental to the continued survival of amphibian species. Most detailed studies of amphibian population declines have identified more than one factor as a cause of decline and, in many instances, multiple factors act synergistically (Blaustein and Kiesecker, 2002).

Habitat Destruction

The single most important factor that adversely affects amphibians is habitat destruction and modification. Many habitats that are essential for eggs, larvae, or adult stages are shrinking or disappearing at an accelerating rate as a result of human population growth and economic development. Tropical forests provide some of the most species-rich habitats in the world and are particularly vulnerable to destruction by humans, with land being turned over to agriculture or to provide residential areas for people. In 1991, the United Nations Food and Agriculture Organization reported that the

Table 1 Number of amphibian species in each of the IUCN categories

Conservation status	Number of species	% of species
Data-deficient (DD)	1294	22.5
Least concern (LC)	2203	38.4
Not threatened (NT)	359	6.3
Vulnerable (VU)	668	11.6
Endangered (EN)	761	13.3
Critically endangered (CR)	427	7.4
Extinct (EX)	35	0.6
Total	5743	

The three categories VU, EN, and CR are grouped together as Threatened (T); this group consists of 1856 species, representing 32% of all known amphibian species. *Source:* Reproduced from Stuart SN, Chanson JS, and Cox NA (2004) Status and trends of amphibian declines and extinctions worldwide. *Science* 306: 1783–1786.

world's tropical forests were being destroyed at a rate that was 50% faster than a decade previously. Tropical forests support a high diversity of amphibian species, many of them still to be described. At the current rate of deforestation, within 30 years all extensive areas of tropical forest, together with their amphibian fauna, will have disappeared.

Amphibians are particularly dependent on freshwater habitats, especially for breeding. The World Wildlife Fund publishes regular reports which suggest that freshwater habitats are the most seriously threatened on Earth. Between 1970 and 2007, the global diversity of freshwater species decreased by 35%, that of tropical freshwater species by almost 70%, a faster rate of decline than has been detected in any other component of the global ecosystem (Pollard, 2010). Although there is legal protection for some of the world's larger lakes and rivers, largely because of their importance in providing fish to support the human population, the smaller streams, ponds, and swamps that are essential habitat for amphibians are generally not protected. The draining of wetlands to make way for agriculture and housing has had a particularly serious negative effect on many amphibian populations.

In much of western Europe, traditional methods of agriculture previously provided good habitat for amphibians in the form of small woodlands, hedgerows, and numerous ponds created to provide water for livestock. In the past 50 years, however, agricultural practices have changed and all these landscape features have been destroyed over very large areas. In parts of Britain, for example, the number of ponds suitable for amphibians to breed in has declined by 90% in the past 50 years.

Habitat destruction in a given area is not always total; often, small pockets of forest, heathland, or wetland are set aside for conservation purposes. This results in the fragmentation of previous areas of habitat and there is increasing evidence that habitat fragmentation is a serious threat to the continued survival of species that it was assumed were afforded some degree of protection. Fragmentation of habitat leads to the isolation of small populations of amphibian species. Inbreeding in such populations reduces their genetic diversity, and their isolation prevents interchange of individuals and thus of genetic diversity, and their isolation prevents interchange of individuals and thus of genetic variation with other populations. As a result, isolated populations tend to decline slowly and eventually die out, even though they are protected. Many amphibians have only limited powers of dispersal, and even a road built through an area of otherwise suitable habitat will reduce dispersal.

Climate Change

There is increasing evidence that the earth's climate is undergoing major changes as a result of human activities such as the destruction of forests. Most notably, average temperatures are steadily increasing in many parts of the world and there are major changes in rainfall patterns. The long-term effects of such changes on amphibians are largely a matter of speculation, but there is evidence that they have had an impact on some species. For many amphibians, rainfall patterns are critical because they determine whether, and for

how long, the small streams and ponds in which they breed contain water.

The apparent extinction of the golden toad (*Bufo periglenes*), along with several other frog species, in the montane forest of Costa Rica appears to be due, at least in part, to climate change (Pounds *et al.*, 1999). A critical factor in the habitat of this species is low-lying cloud, which provides the water that maintains water flow in the small streams in which many of the native frogs breed. The extent of such cloud has decreased in recent years, leading to extensive reductions in the amount of available water and thus a general reduction in stream habitat. In Britain, winters are becoming increasingly less severe and several native amphibians are now breeding earlier in the spring than they were 20 years ago. There is also evidence that common toads (*Bufo bufo*) in Britain are in poorer body condition, and less fecund, following milder winters (Reading, 2007).

Ultraviolet Radiation

The steady erosion of the ozone layer in the earth's stratosphere has led to an increase in the amount of ultraviolet (UV) radiation reaching the Earth's surface. Such radiation, especially UV-B, is harmful to living organisms and there is accumulating evidence that it may be a factor in the decline of some amphibian species, especially those living at high altitudes, where incident levels of UV-B are highest. Increased UV-B causes the genetic material DNA to mutate, leading to the abnormal development and eventual death of embryos. Frog and toad species that lay their eggs close to the surface of water, which filters out UV-B, may be particularly susceptible to increased UV-B. Although there is considerable experimental evidence that ambient levels of UV-B radiation are harmful to the early life stages of amphibians (Blaustein *et al.*, 1995) it is not clear to what extent elevated UV-B has been a factor in the decline of amphibian populations in nature (Alford and Richards, 1999).

Amphibian species vary in their susceptibility to elevated UV-B. Some species, such as the Pacific tree frog (*Hyla regilla*), produce high levels of the enzyme photolyase, which repairs DNA damage of the kind caused by UV-B. This species is one of those that has not declined in the Pacific Northwest of North America, unlike species with lower photolyase levels, such as the Cascades frog (*Rana cascadae*) and the western toad (*Bufo boreas*) (Blaustein *et al.*, 1994). If elevated UV-B does affect natural populations of amphibians, it is likely that it acts synergistically with other adverse environmental factors, such as acidification and pathogens. There is experimental evidence that both these factors have a more detrimental effect on the survival of amphibian embryos when they are combined with elevated UV-B.

Chemical Pollution

Environmental pollution has caused the decline or extinction of some local populations of amphibians, and it is likely that it also has a widespread harmful effect. For example, declines of amphibians in Yosemite National Park in California appear to be due to chemical pollution that has drifted on the wind

from agricultural areas many miles away. Amphibians may provide sensitive biological indicators of pollution because their highly permeable skin rapidly absorbs toxic substances. Examples of pollutants include fertilizers, herbicides, pesticides, heavy metals, and poisoning resulting from logging and mining operations.

A major form of pollution that can affect very large areas is atmospheric acid deposition or acid rain. Much of the rain that falls in regions downwind from major industrial areas, such as in the eastern United States, Scandinavia, and western Europe, is markedly acidic, with a pH of approximately 4.5; unpolluted rain has a pH of approximately 5.6. Acid rain lowers the pH of natural water bodies below the tolerance level of many species of amphibians. The toxic effects of low pH on amphibian development are well-documented. Acidic conditions reduce the mobility of sperm and may cause them to disintegrate, with a consequent reduction in the fertilization success of eggs. Eggs that are fertilized may develop abnormally; if they hatch, they produce deformed tadpoles that soon die. Acid precipitation has been implicated in the declines of tiger salamanders (*Ambystoma tigrinum*) in the Rocky Mountains of Colorado and of the natterjack toad (*Bufo calamita*) in lowland heaths in Britain.

Some chemical compounds of human origin are readily absorbed by animals and interfere with their endocrine systems; these are known as endocrine disrupters and include estrogen mimics, which are compounds that disrupt the reproductive development of both sexes (Stebbins and Cohen, 1995). Males may become feminized to varying degrees, for example, suffering lowered sperm counts and developing ovarian tissue in their testes.

Many pesticides, such as DDT, are not only poisonous to a wide range of animals but also, at low concentrations, have endocrine-disrupting effects. Populations of amphibians in Africa and the USA have been adversely affected by the widely used herbicide atrazine because of its feminizing effects on males (Hayes *et al.*, 2010). Many of these compounds are highly volatile and so are transported very widely in the environment from their point of origin. The long-term effects of widespread chemical pollution of this kind are poorly understood but are very alarming not just for amphibians and reptiles but also for animals of all kinds, including humans.

Another kind of pollution which may affect amphibians in agricultural habitats results from nitrates derived from fertilizers. Recent research has shown that frog tadpoles reared in water containing nitrates at levels low enough to be considered safe for human consumption suffer physical abnormalities, paralysis, and death (Marco and Blaustein, 1999). Nitrate fertilizers are widely used throughout the world and may constitute a serious threat to many amphibian populations.

Disease

Diseases are a natural cause of morbidity and mortality among animals, but very little is known about their role as a determinant of population size among amphibians. In the past few years, however, major outbreaks of disease among amphibians in many parts of the world have occurred, and some

of these have had a major impact on the populations of many species. During the 1990s, mass mortalities occurred among populations of the common frog (*Rana temporaria*) in south-east Britain. These were caused by ranaviruses similar to pathogens that have caused mass mortalities among tiger salamanders (*A. tigrinum*) at several localities in the United States and Canada in recent years (Daszak *et al.*, 1999).

More recently, a disease called chytridiomycosis has become widespread throughout the world, and has wiped out many wild populations of amphibians (Daszak *et al.*, 1999). The disease is caused by a chytrid fungus, called *Batrachochytrium dendrobatidis*, an organism that invades the skin of amphibians. These sudden, major outbreaks of the same, previously unknown disease in widely distant parts of the world raises several questions that are urgently being addressed: Is the chytrid fungus a new organism that has only just evolved? Is it a long-established organism that has recently found its way to these localities and, if so, how? Current evidence suggests that amphibian chytrid is new to at least some parts of the world and that it has been spread, largely by human activities, from Africa.

Commercial Exploitation

Many people in many parts of the world have long eaten amphibians because they are a good and readily available source of protein. Until recently, such exploitation rarely had a serious impact on natural populations because it was localized, seasonal, and of low intensity. Unfortunately, modern commercialization of amphibians for the world's luxury food market is generally done with little regard for the long-term protection of natural populations. Most of the frogs that are killed for human consumption are not a vital component of the diet of local people in the developing world but are a luxury item in the diet of people in developed countries.

The scale of trade in frog legs has long been substantial, but it is beginning to be controlled and reduced. In 1976, 2.5 million kg of frog legs was imported into the United States, mostly from India and Japan. In France, the annual consumption is estimated to be 3000 or 4000 tons, imported mostly from Bangladesh and Indonesia. Until recently, 200 million pairs of legs were exported annually from Asia to the United States, Europe, and Australia; however, since 1987, India has banned this trade because declines in natural frog populations had caused dramatic increases in the densities of insect pests.

The emergence of the disease chytridiomycosis as a serious threat to amphibians has added an additional, urgent reason to curb the international trade in frogs for food. There is strong evidence that chytridiomycosis has been introduced into Europe, on several occasions, on American bullfrogs imported for food.

Products derived from amphibians are constituents of many traditional medicines and are used in many other ways. The skin secretions of poison-dart frogs have been used in hunting by Central and South American Indians, and those of many toad species are used in many parts of the world as hallucinogens. Whether any of these forms of exploitation has had a harmful effect on natural populations is doubtful, but

the future exploitation of amphibians and reptiles could either seriously threaten their continued existence or ensure their survival, depending on how it is managed. There is a lengthening list of compounds, found in the skin of frogs, that have considerable potential as medicines. For example, poison-dart frogs of the genus *Epipedobates* produce a unique alkaloid called epibatidine which is a much more effective painkiller than morphine and that appears not to be addictive.

Introduced Species

As the human population has expanded and people have colonized new parts of the world, they have taken with them, deliberately or accidentally, a variety of organisms that have been harmful to indigenous wildlife. The eggs and larvae of amphibians make easy prey for fishes and other freshwater predators, and many amphibian species are dependent on water bodies that are free of fish to breed successfully. In many parts of the world, exotic fishes have been introduced by humans to the detriment of native amphibians. In California, trout have been introduced, to provide sport fishing, to high-altitude lakes and have caused the decline of several amphibian species; in many parts of the world, mosquito fish (*Gambusia affinis*) have been introduced to control mosquitoes and other insect pests, with equally disastrous results for native amphibians.

Some amphibians have been implicated in the declines of other species where they have been introduced to parts of the world in which they did not previously occur. The most notable example is the marine toad (*Bufo marinus*), a native of Central America, which was deliberately introduced to Hawaii, Australia, and many other places to control insect pests in sugarcane plantations. In Australia, where it is known as the cane toad, it has spread relentlessly outward from the Queensland coast to the detriment of much of Australia's native fauna, including many frog species. The American bullfrog (*Rana catesbeiana*), a native of eastern North America, has been introduced to many parts of the world to be farmed to supply the trade in frog legs, and it has had a harmful effect on many native frog species both because it is a greatly superior competitor and because it is a predator of smaller frogs.

Declining Amphibian Populations

In the Monteverde cloud forest reserve in Costa Rica, the formation of large mating aggregations of the spectacularly colorful golden toad (*Bu. periglenes*) used to be an annual event. In 1989, however, this species failed to appear and it has not been seen since (Pounds and Crump, 1994). The golden toad has become the icon of the declining amphibian phenomenon, but it is only one of many species throughout the world that have disappeared because of this deeply disturbing process. The Monteverde reserve was established to protect biodiversity and yet, since 1990, 40% of its native frog and toad species have disappeared (Pounds *et al.*, 1999). Similar catastrophic declines of amphibian populations in supposedly pristine, protected habitats have occurred in Queensland, Australia, the Atlantic forests of Brazil, and the

Pacific Northwest of North America. In a section of California's Sierra Nevada that includes Yosemite National Park, five of seven amphibian species have seriously declined in recent years. In protected remnants of tropical rain forest in eastern Queensland, 14 species of stream-dwelling frogs have drastically declined or totally disappeared. These events carry a disturbing message for conservationists: As one scientist said at a recent workshop on amphibian declines, "locking up nature just isn't working."

Although it is clear that the majority of the world's amphibians that have declined or become extinct in the past 50 years have done so as a result of habitat change or destruction, these declines in protected areas suggest that some other kind of process is adversely affecting amphibian populations. Because of their dual life history, spent partly in water and partly on land, and because none of their life stages (egg, larva, or adult) have the kind of protective covering possessed by animals such as insects, reptiles, birds, and mammals, it has been argued that amphibians are especially sensitive to environmental insults such as chemical pollution (Stebbins and Cohen, 1995). According to this argument, amphibian declines may be the prelude to an environmental catastrophe that could affect many forms of life. Like the coal miner's canary, frogs may be providing an early warning to all biodiversity.

It is becoming increasingly clear that this kind of argument is not applicable to all amphibians. Indeed, a feature of all the declines that have occurred recently in supposedly protected habitats, such as Monteverde, is that although some species have declined or vanished, others have been quite unaffected. It is not clear, however, what character or characters differentiate amphibian species that have declined in pristine areas from those that have not. Amphibians are a very diverse group of animals in terms of their habits, their life histories, and their physiology. For example, although some species do have a highly permeable skin and are extremely sensitive to pollutants, for others the skin is highly effective as a protective covering. The American bullfrog (*R. catesbeiana*), for example, seems to be remarkably resistant to the effects of pesticides.

Possible Link with Deformities

Since a group of children found some severely deformed frogs in Minnesota in 1995, there has been much media attention devoted to this phenomenon in the United States, often making a link with amphibian declines there and elsewhere. These deformities reflect abnormalities in development and include missing eyes, digits, or entire limbs as well as extra limbs, sometimes growing from unexpected parts of the body. There are several reasons for being cautious about a possible link between deformities and the global decline phenomenon, however. First, such deformities are not new but rather have been reported periodically for more than 200 years, especially in the mid-northern United States. Second, although reports have become more frequent recently, there is no reason to believe that deformed frogs have become more common; there are simply more people looking for them. Third, developmental abnormalities are caused by a variety of natural causes, including parasites and injury following attack by

predators, as well as by anthropogenic factors, such as chemical pollution and increased UV-B radiation.

Deformed amphibians are a cause for concern because they are often symptomatic of local environmental degradation. Before we can conclude anything of wider significance from them, however, we have to remember that they are both naturally occurring and typical of amphibians and that they do not represent a new phenomenon. Only additional research into the role of various pollutants and of UV-B into the development of deformities can reveal to what extent they are another facet of processes that are adversely affecting amphibians on a global scale.

Glossary

Reptile Member of a class of vertebrates (the Reptilia), comprising turtles and tortoises (order Testudinata), lizards, snakes, and worm-lizards (order Squamata), the tuatara

(order Rhynchocephalia), and crocodiles and alligators (order Crocodylia), which typically lay eggs with a leathery, impermeable shell. Reptiles have a dry, horny skin with scales, plates, or scutes.

Reptiles

Reptiles are ectothermic, meaning that the heat that they require to maintain physiological processes is derived externally, directly or indirectly from the sun. Reptiles are the ancestors of birds and the mammals, both of which are endothermic, meaning that body heat is primarily generated within their bodies. Their dependence on the external heat sources limits reptiles to tropical and temperate regions of the earth and they are especially numerous in the tropics. Reptiles are found in all continents of the world, except Antarctica, living in a wide variety of habitats, including the world's driest deserts. Many are aquatic, living in both fresh water and the sea.

The skin of reptiles is covered in impermeable scales and they are able to retain water very effectively. Their eggs are covered by a hard shell, providing a sealed environment for the developing embryo, which does not depend on external sources of water. These two features have enabled reptiles successfully to colonize very dry habitats, including deserts. While tortoises are typically slow and ponderous in their movements, many reptiles are very agile and capable of moving very fast, often over large distances. Marine turtles, in particular, routinely undertake enormous journeys across the world's oceans.

Reptiles are divided into six major groups: The worm-lizards (*c.* 181 species), the lizards (*c.* 5461 species), the snakes (*c.* 3315 species), the turtles and tortoises (*c.* 317 species), the alligators and crocodiles (*c.* 23 species), and the tuataras (two species).

The Conservation Status of Reptiles

A comprehensive review of the conservation status of reptiles, like that of amphibians, has yet to be made, but reptile species are monitored by the World Conservation Union (IUCN) and by the Convention on International Trade in Endangered Species (CITES) (see [Table 1](#)). The latter is important because commercial exploitation is a particularly serious threat to many reptile species.

Threats to Reptiles

Many reptile species have become endangered by human activities that affect them either directly or indirectly. Direct impacts include the widespread persecution of snakes, whether or not they are venomous, killing of turtles and some lizards for food, and collection of tortoises, lizards, and snakes for the global pet trade. Indirect effects include habitat destruction, climate change, and pollution.

Habitat Destruction

Those reptiles that spend all or part of their lives in fresh water, such as alligators, crocodiles, turtles, and water snakes, are threatened in many parts of the world by the draining of wetlands. Some regions of the USA retain less than 20% of their original wetlands and numerous aquatic and semiaquatic reptiles have declined as a result. In Australia, destruction of

Table 1 Conservation status of reptiles, according to the Convention on International Trade in Endangered Species (CITES) and the World Conservation Union (IUCN)

Taxon	CITES ^a				IUCN		
	Approximate number of species	Appendix III	Appendix II	Appendix I	Vulnerable	Endangered	Extinct
All reptiles	7150	19	383	70	153	100	20
Turtles and tortoises	260	6	49	25	58	38	6

Source: Data from FWS (2000).

woodland and scrub to create agricultural land has been the major cause of population declines among snakes. Declines among reptiles as a result of deforestation have been particularly marked on Madagascar.

Roads present a particular risk to reptiles, not only because they have to cross them as they move about, but also because they are attractive places to bask in the sun. Large numbers of snakes, tortoises, and lizards are killed on roads. In some turtles, females are at greater risk than males, apparently because they move about more than males.

Animals of all kinds that live on small oceanic islands are especially vulnerable to extinction, and reptiles are no exception. Island species are often very vulnerable to introduced predators, such as rats, cats, dogs, and mongooses, having evolved in an environment in which such predators were previously absent. Small islands are also highly susceptible to habitat destruction and excessive hunting. Among endangered reptiles that live on islands are giant tortoises such as those found on Aldabra and the Galapagos.

Some reptiles are vulnerable to exploitation by humans and to natural predation because they gather to breed in large numbers. A marine turtle, Kemp's ridley (*Lepidochelys kempi*), was reduced to near extinction in the 1970s by the commercial exploitation of breeding females and eggs, gathered at their coastal breeding sites in Mexico and Texas. This species is now internationally protected and its numbers are recovering.

Migratory species, such as some sea turtles, are very vulnerable both because their conservation requires that they be protected in several, often distant, parts of the world and because they have to make long journeys across possibly hazardous environments. The green turtle (*Chelonia mydas*), for example, is protected in Australia but is exploited in Indonesia. Leatherback turtles (*Dermochelys coriacea*) nesting in Gabon in central Africa undertake huge journeys across the Atlantic, to South America or to southern Africa. Satellite-tracking has revealed that one female leatherback traveled 7563 km between a feeding area off South America to her nesting site in Gabon (Witt *et al.*, 2011). Such long journeys take turtles through many areas where they are in danger of being caught by fishermen. As a result, their effective conservation would require active cooperation by at least 11 different nations.

Commercial Exploitation

Throughout human history, reptiles have been used by people for a variety of purposes. Apart from being a food source, tortoise shell is used for decorative purposes. Snake, lizard, and crocodile skins are used to make shoes, belts, and handbags, and the flesh of many reptiles is believed to have medicinal or aphrodisiac properties.

In some parts of the world, there is also a substantial trade in reptile meat. Between 1979 and 1987, the hunting of alligators in Louisiana yielded 45,000 kg of alligator meat each year. Many turtles are heavily exploited as a food source, both by indigenous people and the markets in developed countries to supply luxury food. In Asia, the trade in turtles for food and medicines has reached crisis proportions, with 67 of 90 species categorized as threatened and 18 as critically endangered.

The green iguana (*Iguana iguana*) has declined severely as a result of being hunted for food. Eaten by humans in Central America for centuries, destruction of its habitat and the expansion of the human population have led to it being hunted much more intensely in the past 30 years. In the late 1960s, as many as 150,000 iguanas were eaten each year in Nicaragua alone. Not only is iguana flesh regarded as a great delicacy but also their fat and eggs are used for a variety of medicinal purposes, including a cure for impotence.

The adverse effects of the overexploitation of natural populations can, in some cases, be countered by sustainable farming. There is now a thriving trade in American alligators (*Alligator mississippiensis*) with more than 30 farms in Florida providing more than 136,000 kg of alligator meat and 15,000 skins each year.

The highly durable skin of reptiles makes it an excellent alternative to leather, and reptile skins have long been used for making footwear, purses, belts, and many other accessories. Many species of pythons, boas, varanid lizards, and crocodiles are declining because they are hunted for their skins. In 1981, the USA imported 304,189 pairs of shoes made from boa skin and 176,204 pairs of python skin shoes. In the absence of commercial breeding programs for these species, this trade was entirely based on the exploitation of wild populations. Today, trade in reptile skins is increasingly regulated and sustained by breeding animals in captivity, but there remains a substantial illegal market in skins derived from natural populations.

Products derived from reptiles and amphibians are constituents of many traditional medicines and are used in many other ways. Broths made from snakes and tortoises are believed to combat many diseases; the fat of monitor lizards (*Varanus* spp.) is used to combat skin infections; sea turtle eggs are used as aphrodisiacs; turtle oil is used to make perfumes and lubricants.

Introduced Species

As the human population has expanded and people have colonized new parts of the world, they have taken with them, deliberately or accidentally, a variety of organisms that have been harmful to indigenous wildlife. This is a particularly serious threat to species living on small islands where, in the absence of indigenous predators, they have lost their defense against predators. Populations of many reptile species that are endemic to islands have been devastated by the introduction of alien rats, cats, dogs, and other animals that feed on them or their eggs, and introduced pigs and goats have destroyed the ground cover that supports their food supply and which they need to escape from predators.

The tuataras (*Sphenodon*) have become extinct on the two major islands and on many of the smaller islands of New Zealand and are now confined to a very few small islands that remain free of alien immigrants. Intensive efforts are now being made to clear other islands of predators and prevent further releases of alien species. In addition, tuatara eggs are being incubated in captivity and the resulting lizards are being released across the various protected islands in such a way as to maintain genetic diversity in these small populations (Keall *et al.*, 2010).

The rarest lizard in the world is the Jamaican iguana (*Cyclura collei*). Believed for many years to be extinct, as the result of predation of eggs and young by introduced mongooses, a tiny population was rediscovered in 1990. A population of 100 to 200 animals is now being sustained by protection of its habitat, exclusion of mongooses, and captive breeding.

Some reptiles are themselves invasive species. Brown tree snakes (*Boiga irregularis*), accidentally introduced onto the island of Guam from their native Australia and Papua New Guinea, have seriously reduced or extirpated not only populations of endemic birds but also several native reptiles.

Climate Change

For reptiles, temperature is crucial because many species rely on basking in the sun to raise their body temperature to a level at which they can carry out the essential activities such as feeding and reproduction. Consequently, future climate change is likely to pose a serious threat to many reptile species. It has been predicted that this threat is most serious for tropical species, even though temperature increases are predicted to be less marked at tropical than at temperate latitudes (Deutsch *et al.*, 2008). This is because many tropical reptiles are currently living very close to the maximum temperature that they can tolerate. In contrast, many temperate reptiles are currently living in climates that are cooler than what is optimal for them and they may benefit from future climate change. However, because reptile diversity is much higher in the tropics, more species are likely to be adversely affected by climate change than will benefit from it.

Climate change is likely to affect reptiles in a more subtle way, because sex-determination in many reptiles is strongly influenced by the temperature at which their eggs develop. The details of this process vary across different groups of reptiles. In many turtles, low temperatures produce male offspring, high temperatures females; the reverse is true in some lizards. In crocodiles and alligators, low and high incubation temperatures produce females, while intermediate temperatures produce males. These effects have been intensively studied in the laboratory, but there is evidence that they may affect wild populations. Studies of painted turtles (*Chrysemys picta*) have revealed that small increases in air temperature during July reduce the proportion of offspring that are male (Janzen, 1994). Extrapolating from these results, it is predicted that an increase in mean temperature of 4 °C would effectively eliminate the male offspring altogether.

Pollution

Pollution in the form of solid plastic waste is harmful to some sea turtles that may eat it. Green turtles (*Chelonia mydas*) eat plastic bags while feeding on aquatic plant food and leatherback turtles (*Dermochelys coriacea*) mistake plastic bags for their jellyfish prey. Half of the sea turtles examined in some

localities have plastic debris in their intestines. This may interfere with their digestion, respiration, and buoyancy, and some plastics are toxic.

Some chemical compounds of human origin are readily absorbed by animals and interfere with their endocrine systems; these are known as endocrine disrupters and include estrogen mimics, which are compounds that disrupt the reproductive development of both sexes. Males may become feminized to varying degrees, for example, suffering lowered sperm counts. Reptiles are especially susceptible to such effects because of their sex-determination mechanisms which, in many species, are very dependent on environmental factors. Of particular concern are the polychlorinated biphenyls (PCBs), industrial chemicals such as those used in fire retardants and adhesives, which persist for a very long time and accumulate in the environment. Some PCBs have a molecular structure so similar to estrogen that they mimic its effects when they enter an animal's body. PCBs can turn male red-eared slider turtles (*Trachemys scripta*) into females, drastically reducing the reproductive success of populations.

Many pesticides, such as DDT, are not only poisonous to a wide range of animals but also, at low concentrations, have endocrine-disrupting effects. Populations of alligators in Florida have been adversely affected by such compounds because of their feminizing effects on males. Many of these compounds, including PCBs, are highly volatile and so are transported widely in the environment from their point of origin. The long-term effects of widespread chemical pollution of this kind are poorly understood but are very alarming not just for reptiles but also for animals of all kinds, including humans.

Glossary

Aquaculture Commercial farming of aquatic organisms, including seaweeds, raising captive-bred fish, and raising wild-born fish in captivity. Mariculture refers specifically to marine (saltwater) aquaculture.

Ballast Water taken in by ships to balance them after they have unloaded their cargo.

Bycatch Any living thing caught unintentionally in fishing gear; sometimes called bykill because so many such creatures are discarded dead.

Depletion In fisheries, reduction in population levels low enough to reduce or threaten future productivity.

Fishery A collective effort to gather, collect, or catch wild aquatic wildlife or plants for recreational or commercial purposes. Fisheries extract large numbers of wild fish, sea

urchins, corals, seaweeds, shrimp, snails, clams, scallops, squids, turtles, whales, and other creatures.

High seas Parts of the ocean outside national boundaries, usually beyond 200 miles of any nation's coast.

Keystone species Species whose removal causes a chain or cascade of ecological effects among other species.

Marine reserves Designated areas where no fishing, mining, or other consumptive use is allowed, usually for purposes of replenishing nearby fishing grounds or maintaining normal evolution, growth, and fecundity.

Overfishing Extracting marine organisms faster than they can reproduce.

Pollution Introduction of substances in quantities that are threatening to living resources, biological processes, and human health and activities.

Outline

Overfishing and habitat degradation have driven many fish populations to historic lows. Poor fisheries management, increasing human population pressures, and habitat deterioration from several factors have caused this situation. But many fish are resilient and can recover within a decade or two if given viable habitat and a respite from overfishing.

Introduction

An ocean of water covers more than 70% of the Earth, and travelers from another world might more logically assume that this planet would be named Ocean. Ninety-seven percent of Earth's water is in the ocean (2% is locked up as ice, and 1% is in surface freshwater or groundwater). Moreover, 99% of the living space on the planet in which life can exist – the biosphere – is in the sea. The basis of most life in the sea are the plant-like single-cells called phytoplankton that create food from sunlight (through photosynthesis) and drift in the upper 1% of the ocean's volume. Plants attached to the bottom can only live in shallow coastal areas where they can get enough sunlight. Most life in the other 99% of the sea relies on food coming from that thin upper layer. Of 36 living animal phyla (the category that reflects the different basic body plans of living things), 34 are found in the ocean, 16 exclusively so. This article focuses on the world's ocean fishes. (For a synopsis of biodiversity issues facing freshwater fish, see [Box 1](#)).

The World Ocean Fishing Situation

Many factors affect life in the sea, and though climate warming and changes in ocean acidity due to fossil fuel combustion causes deep and fundamental change, fishing has caused the

largest and most noticeable changes in ocean wildlife populations to date. The United Nations' Food and Agriculture Organization has stated that modern fishing "is globally unsustainable."

During the last century, annual landings of wild ocean fish increased 25-fold, from 3 million metric tons to a plateau of over 80 million metric tons ([FAO, 2010](#)). In the 1950s and 1960s, fishing technologies exploded as fishing fleets adapted war technologies such as radar, sonar, and Long Range Navigation (LORAN) to peaceful efforts of food gathering. Radar allowed boats to keep fishing in total fog, and sonar could find schools of fish deep beneath the sea's surface. LORAN and, later, Global Positioning System (GPS) turned the trackless sea into a grid and allowed boats to find and return to precise spots where fish gather. Satellite-generated maps faxed directly to boats in mid-ocean now track movements of water temperature fronts, showing where to find the fish ([Safina, 1995](#)).

Overfishing, scarcely recognized in the early 1900s, is now prevalent in most major fishing areas. The proportion of overfished populations is increasing, from 10% in the early 1970s to over 30% today ([FAO, 2010](#)). Not all of the catch is used for food. About a third of the world's catch becomes fertilizers, animal feeds, and industrial products, and about 7 million tons each year is unwanted and shoveled overboard.

World fish landings peaked in the late 1990s, but many fisheries reached the limit decades earlier. Indeed, most regions in the Atlantic, Mediterranean, Pacific, and even Antarctic have declining catches. In some regions where catches peaked as long ago as the early 1970s, catches have declined by half. Declines in some individual fisheries have been catastrophic. Newfoundland cod, which supported one of the world's largest fisheries for over 400 years, crashed 99% between the early 1980s and early 1990s. Many other fish

Box 1 Synopsis of freshwater biodiversity issues

Worldwide, lakes and rivers contain at least 10,000 fish species, roughly 40% of known fish species on Earth, and almost 20% of all vertebrates (freshwaters support almost one-quarter of the planet's known biodiversity, in only 0.01% of the planet's water; however, the oceans hold vastly larger populations).

Lakes are isolated habitats, leading to a high rate of evolution of species of fish and other animals. For instance, three-quarters of the 2000 plant and animal species in Russia's Lake Baikal are found nowhere else. The lakes of Africa's Rift Valley have produced explosive speciation – 99% of the 500 cichlid fish in Lake Malawi, for instance, live nowhere else. And Lake Tanganyika, the least-species-rich lake in the Rift Valley lake chain, has 25% more species of freshwater fishes than all of Europe.

Freshwaters are being degraded and species eliminated at a rate probably comparable to that occurring in tropical rain forests. Habitat loss and introduced species are the two greatest problems for freshwater biodiversity. Introduced predatory fish have already wiped out nearly 70% of Lake Victoria's cichlid fishes, and greatly reduced total biomass and productivity in the lake. In the USA, half the rivers and streams are significantly polluted, and 98% of US rivers outside Alaska are partially blocked by dams. Consequently, 40% of fish species and almost 70% of mussel species in US freshwaters are endangered or have become extinct, in contrast with only 15% of the mammals and birds in the USA.

Of the world's estimated 10,000 freshwater fish species, about 20% are in serious decline or have gone extinct. Ecologist Norman Myers has called the freshwater fish situation "the greatest extinction spasm of vertebrates in recent times." Climate Change will further negatively impact freshwater fish, and it's likely that many species will be unable to adapt or disperse to favorable environmental conditions.

populations have declined by 80% or more (Casey and Myers, 1998). Some major fishing grounds are now closed in hopes that the fish will recover. Most important ocean wildlife used as seafood are considered fully exploited or overfished (FAO, 2010), and no major untapped fishery resources remain in the world. Humanity's former faith in the sea's inexhaustibility was wrong.

Social and Economic Concerns

Worldwide, 180 million people depend on fishing and aquaculture for their livelihoods (FAO, 2010). Marine fishing supplies 16% of all animal protein consumed worldwide. Annual global fish consumption increased from 10 kg per person in the 1960s to over 17 kg today.

In the last few years, many thousands of fishers around the world have experienced severe decline or loss of their source of income. Depletion, caused primarily by industrial overfishing and exacerbated by coastal habitat degradation, threatens tens of millions of jobs as well as major food sources. As preferred species are fished out (Pauly *et al.*, 1998), and less-preferred fish are targeted, prices rise for these less-preferred fish. Price increases eventually remove the species from the tables of the poor. Distant markets and increasingly globalized trade networks allow and encourage regional overfishing or irresponsible aquaculture that exhausts local resources. This results in serial depletion and habitat degradation along faraway shores. For example: Bluefin tuna are depleted in the Atlantic and Mediterranean, and off Australia and New Zealand, because of the demand in Tokyo, where they have become the world's most expensive sushi (Safina and Klinger, 2008); appetites in the Northern Hemisphere support destructive shrimp farms in the tropics; and shark populations are declining in many places around the world because of demand for their fins, primarily in China.

Management Problems

In most of the world, intense political lobbying by the fishing industry usually causes fishery managers to disregard scientific assessments and scientific advice to bring catches within sustainable limits.

While no group of fishes is exempt, Atlantic bottomfishes such as cod, flounders, and Atlantic halibut have been among the worst managed. Various species of groupers and wild salmon are depleted throughout most of their ranges. Overfishing has driven many large fishes in the Atlantic to all-time lows. The Atlantic tuna commission's mismanagement, labeled an "international disgrace" by an independent review (ICCAT, 2009), has resulted in systematic overfishing of many tuna and marlin populations. The world's giant fishes – the tunas, billfishes (like swordfish and marlins), and sharks, among the most magnificent of the ocean's wildlife – are also among the most mistreated. In much of the world, management in these fisheries is lacking or ineffective. Sharks, subject to intense overfishing in many regions, are easily depleted because they are generally slow growing with low reproductive rates. Fishing annually kills tens of millions of sharks worldwide, mostly just for their fins, which are prized as a thickener in "shark fin soup." Only 7 of 20 major shark-fishing countries have management and research programs.

In many other cases, poor monitoring or outright cheating enlarges the gap between fishery science and fishing activities. In one 7-year period, foreign fleets fishing the Grand Banks removed sixteen times the quotas that had been set for cod, flounders, and redfish by the Northwest Atlantic Fisheries Organization. A seized Spanish boat kept two log books – one showing actual-catches and one for reporting to the authorities.

Few countries are successful in fisheries management whereas most are hardly trying. International cooperation on migratory populations and fishing outside national waters – on the high seas – is particularly difficult, and in some cases a country unhappy with the restrictions of an agreement has simply ignored them outright or through lack of enforcement.

Fish Fights: International Fishing Conflicts

Fish conflicts, many of them violent, have erupted around the world. Norway, Iceland, the United States, Canada, Indonesia, Taiwan, Nicaragua, Russia, China, the Philippines, Japan, France, Britain, Spain, and many others have been involved in international fishing disputes. In disputed waters off the Philippines, Chinese vessels were seized and scores of crew members were jailed. In the Galápagos, troops were deployed after

fishers seized a biological station that was trying to stop rampant illegal fishing inside a marine reserve. In France, fishers protesting fish imports rioted, causing \$4.5 million in damage. NATO allies have pointed guns at each other in disputes over cod, and a Russian Navy boat fatally shot Chinese poachers. Hundreds of Indonesian fishermen have been imprisoned for fishing illegally in Australian waters. More trouble is likely as hungry boats scour the oceans for dwindling resources.

Fish as Commodities/Fish as Wildlife

Marine creatures are wild animals still hunted commercially on a large scale. And we usually treat fish as mere commodities, forgetting that fish are wildlife. For instance, we speak of a population of fish as “stock,” as in “the New England groundfish stock.” We would not speak of the “Serengeti mammal stock” or the neighborhood “woodpecker stock.” By preventing us from seeing fish as wildlife in natural ecological communities, the language used helps facilitate their overexploitation.

Probably the most abused word throughout fisheries is harvest. Until recently, humanity has distinguished between hunting and gathering wild things that we do not grow, and agriculture, in which we raise and harvest crops that we do grow. Nowadays, many people try to blur this distinction by using harvest to describe hunting and gathering operations as a way to put a better face on taking large quantities of individuals from wild populations, usually for profit. We usually do not say we have harvested agricultural animals like cows, pigs, and chickens when we slaughter them for meat, even though we raise them for those purposes. So why should we say that we harvest wild animals like cod or sharks? Industry people even speak of harvesting whales to avoid using the obviously correct word, hunting, for the pursuing and killing of wild mammals, in this case the largest animals that have ever lived. When a wild fish or whale or a naturally growing tree is simply taken from a wild community, harvest is the wrong word. Appropriate words include: catch, fish for, take, extract, land, gather, collect (e.g., oysters), boat (i.e., they boated many salmon), cut, or hunt.

Intensity and Limits of Fisheries

Humans exert tremendous pressure on the seas. The coasts, where nutrients continually enter the marine environment primarily from the land, are the most productive parts of the oceans by far. The coastal areas, representing only 10% of the oceans’ total area, produce 90% of the world catch (Pauly and Christensen, 1995).

Many industrialized fishing ships deploy large-scale fishing gear such as longlines that are 50 miles long with thousands of baited hooks, drift nets 40 miles long (now subject to a United Nations ban), and bag-shaped trawl nets sometimes large enough to engulf 12 Boeing 747 jetliners.

Since 1970, the world’s industrialized fishing fleet increased at twice the rate of the catch, doubling in number and tonnage. The fleets of the world, numbering 4.3 million vessels (FAO, 2010), now wield twice the fishing power needed to catch what the oceans can produce. If the fleets had not grown at all since 1970, they would be able to catch the same number of fish. Fishing has either reached or exceeded natural limits virtually everywhere in the ocean.

Kinds of Overfishing

Overfishing is the main reason fish populations have declined. Overfishing means catching marine creatures faster than they can reproduce. The global proportion of overfished fisheries has steadily increased, from 10% in 1974 to 32% in 2008. “Fisheries” extract large numbers of wild fish, shrimp, snails, clams, scallops, squids, sea urchins, corals, seaweeds, turtles, whales, and other kinds of creatures. Different kinds of overfishing have been identified (see Box 2), and various factors that can influence a species’ vulnerability to overfishing is seen Box 3.

Overfishing causes: (1) massive depletion of many species; (2) loss of breeders, thus fewer young produced and increased risk of reproductive failure in times of poor environmental conditions (e.g., unusual ocean temperatures); (3) declines in average sizes of fish and other marine creatures; (4) loss of genetic diversity; (5) genetic change toward less desirable characteristics like smaller size potential; (6) disruption of natural communities; and (7) disruption of human communities. Simultaneous overfishing of many species leads to functional loss of species or species groups. Keystone species are those whose removal causes a chain or cascade of ecological effects. For example, removal of algae-eating fishes can cause coral reefs to be killed by algae overgrowth, a large problem in many tropical regions.

Until recently, one of the main assumptions in fishery management was that the number of young produced is generally not related to the number of breeders, and many practicing managers who were taught this in school still believe it. The reasoning was that environmental factors cause a different percentage of young to survive from year to year, regardless of the number of eggs laid. But because any surviving fraction (say, 1%) of a large number of eggs is a higher

Box 2 Different kinds of overfishing affect many species

“Growth overfishing” is when too many fish are caught while very small. In species like groupers that change sex with age, a critical shortage of one sex can result.

“Recruitment overfishing” is reproductive failure due to depletion of breeders.

“Demographic overfishing” turns a population with many age groups into a population with only one or two significant age classes doing most of the breeding, making the population vulnerable to years when natural fluctuations cause poor survival of young.

“Genetic overfishing” is when intense fishing changes a population’s gene pool.

“Serial overfishing” is the depletion of one targeted species after another.

“Ecosystem overfishing” causes great changes in species composition and functional loss of key species, and can result in long-term community changes.

Overfishing related directly to the increasing human population is sometimes called “Malthusian overfishing.”

Box 3 Consideration of these factors can help us assess the vulnerability of a species to overfishing:

1. Inherent vulnerability: Does the species have low growth rate, low fecundity, high catchability (especially while immature), vulnerable behavior (e.g., spawns in groups), vulnerability to environmental changes, increasing vulnerability due to changes in fishing technology, or a poorly understood life cycle?
2. Human-related environmental risk: Does the species suffer destruction of key habitats, widespread effects of pollution, or conflicts with introduced species?
3. Is the population large or small, lightly or heavily exploited?
4. Is there management? Does it involve long-term conservation and sustainability as a goal? Does it benefit from independent and objective scientific advice? Does it have effective mechanisms for monitoring and enforcement and data collection?

number of survivors than the same percentage of a small number of eggs, the assumption that number of young are not related to number of parents is illogical. In 1996, Ransom Myers and Nicholas Barrowman proved this assumption wrong (Myers and Barrowman, 1996). They studied nearly 400 data sets from different species and asked the following questions: (1) Are the largest groups of young fish entering a fishery produced by the highest populations of spawners? (2) Are the smallest groups of young fish entering a fishery produced by the lowest populations of spawners? (3) Are above-average groups of young fish entering a fishery produced by above-average populations of spawners? Their findings: The answer to all three questions is almost always 'yes'.

When fishing is reduced, many depleted populations can recover. When fishing ceased in the North Sea during the world wars, fish populations increased significantly. On the East Coast of North America, a spectacular recovery of striped bass followed strict limits on fishing. Subsequent limits on fishing for several other species have also resulted in increases in those populations. Protecting fish until they reach average spawning age is one of the simplest, fastest, most effective ways to allow recovery.

Bycatch

Every fishery catches unintended, unwanted creatures, called bycatch. Bycatch includes nontarget and juvenile fishes, seabirds, marine mammals, sea turtles, and any other creature that the fishers are not trying to catch. Many die. This source of mortality currently threatens several species of dolphins and albatrosses with extinction.

By weight, about 8% of the animals caught worldwide are discarded (FAO, 2010). By number, a much higher percentage are thrown away, because usually it is smaller fish in the catch that are discarded. In many fisheries, bycatch exceeds target catch. Shrimp trawling incurs more bycatch than any other fishery. Dead discarded catch can outnumber shrimp catch by 15 to 1. Shrimp trawls are the largest human source of mortality to adult sea turtles. Gulf of Mexico shrimp fishery

annually kills and discards 25–45 million juvenile red snappers, about 10 times the number of fish caught in directed commercial and recreational red snapper fisheries and several thousand tons of juvenile sharks. Total discard weight of all animals from the Gulf of Mexico shrimp fishery is almost 500,000 tons. But waste is not the only issue. Using everything caught would not fix the biological effects of killing millions of young fishes, as well as breeding-age seabirds, turtles, dolphins, and other mammals.

Lost fishing gear also catches, kills, and wastes sea life (this is called ghostfishing). Gill nets are frequently lost. For instance, the drift gill net (drift net) fishery of the North Pacific, which set approximately 30,000 miles of netting per night before the United Nations banned it, lost roughly 6000 miles of netting annually. A Norwegian study concluded that lost gill nets continued killing fish for at least 7 years; a New England study found them still catching fish 3 years after they were lost. Lost fishing gear frequently tangles seabirds and marine mammals even in areas as seemingly remote as the Antarctic (see Boxes 4 and 5).

Subsidies and Economics

Because there are too many boats (4.3 million in 2008), fisheries are said to be globally overcapitalized, and many are unprofitable. Worldwide, to catch \$94 billion dollars' worth of fish, governments provide subsidies conservatively estimated at US \$30–34 billion per year (Myers, 1997; FAO, 2010). Such massive subsidies arise from governments' efforts to preserve employment. Subsidies include fuel tax exemptions, price controls, low-interest loans, free access, and outright grants for gear or infrastructure.

Subsidies are responsible for building more fishing power than the resources can support, which increases political and social pressure for continued high catches. But high subsidies can only lead to greater and greater economic distress and further depletion. The United Nations Environment Program estimates that overfishing and overcapitalization results in economic loss of \$50 billion each year. The ecologist Norman

Box 4 Albatrocities

Bycatch from commercial fishing operations is the most serious threat facing albatross populations. Each year over one hundred million hooks are set on longlines in the Southern Ocean. A longline can bear as many as 3000 baited hooks. Albatrosses often congregate in the same areas where boats fish. As the line is being played out from the moving vessel, albatrosses sometimes pick up the bait just before the weight of the sinking line pulls them underwater. This results in the death of tens of thousands of albatrosses and other seabirds each year (Brothers *et al.*, 2010). According to the World Conservation Union (IUCN), 17 of the 21 Albatross species are now threatened with extinction.

Box 5 Dolphin-safe's downside

After several Pacific dolphin populations fell 50–80% due to drowning in tuna nets, the US adopted a “dolphin-safe policy” in 1990, which barred the import of tuna caught by setting nets around dolphins (yellowfin tuna and dolphin swim together in the eastern tropical Pacific). Consequently, dolphin kills dropped 99%, but other bycatch increased. One study found that the average bycatch from 1000 tuna net sets around dolphin herds includes 500 dolphins, 52 billfish, 10 sea turtles, and no sharks. In contrast, average bycatch from 1000 sets around floating objects (where tuna also gather), the preferred fishing method in the wake of the “dolphin-safe” regulations, includes only 2 dolphin, but also 654 billfish, 102 sea turtles, and 13,958 sharks. In addition, large numbers of the tuna caught under floating objects are juveniles.

Myers (1997) concludes, “Subsidies are far and away the principal cause of overfishing.”

Fishery depletion currently costs the US economy \$1 billion and tens of thousands of jobs each year. Rebuilding depleted populations of just four fish species in the US would generate an additional \$570 million per year. Many studies conclude that what are needed are reductions in fishing power – fewer and smaller-scale boats, each employing more people per unit of horsepower – if we are to let the fish populations rebuild.

Other Factors Affecting Fish Conservation

As discussed so far, fishing is currently the major agent of change in the oceans, but a fuller compilation of the major threats to marine biodiversity includes:

- above-discussed fishing operations, which cause depletion, catch large numbers of nontarget species, degrade seafloor and coral reef habitats, and cause major changes in living communities throughout the world's oceans;
- distant markets, which exert tremendous pull on resources from around the world, cause economic, social, and ecological effects of local depletion, then switch to new sources;
- pollution from those chemicals that cause toxic effects and hormonal disruption;
- pollution from excessive nutrients, which increase the frequency and severity of harmful algal blooms such as red tides and brown tides, and cause oxygen-depleted dead zones;
- physical habitat alterations, including development, wetland alteration, and on-land deforestation, which sends clouds of sediments into rivers and coral reefs;
- introductions of species to areas where they are not native, causing competition, predation, and spread of disease;
- aquaculture or “fish farming,” which too often entails extensive habitat damage, pollution, and introductions of alien species and diseases;
- debris, which tangles, traps, or is ingested by large numbers of marine fishes, mammals, birds, and other creatures;
- dams in rivers, which prevent fishes such as certain salmon, sturgeons, river herrings, and others from reaching spawning areas, or kill their young on their way to the sea;
- atmospheric warming from increasingly concentrated carbon dioxide and other greenhouse gases resulting mainly from burning fossil fuels, which stresses corals, lowers overall ocean productivity, melts polar ice, threatens to raise sea level and inundate coastal wetlands and low

islands, and may change ocean current patterns, resulting in changes in abundance and distributions of marine wildlife;

- ocean acidification, resulting from the oceans absorbing high levels of carbon dioxide, causing seawater pH to drop affecting all marine life; and
- ozone thinning, which lowers ocean productivity by killing significant amounts of plankton.

We should bear in mind that gravity takes things from land to sea. Almost everything that enters a storm drain or river goes into the ocean, from used oil to litter. The fewer chemicals people use on their lawns and farms, the less of it we will swim in and eat in our seafood. More oil enters the ocean from urban runoff, including automobile leaks, than from large tanker spills. About three-quarters of ocean pollution comes from the land.

Human Population Growth

By 2050, 9 billion people will be joining you for dinner, and the seas will feel their impact directly. Each year the world adds 70 million new human appetites. To keep pace for just the next 20 years, we will have to find 27 million more tons of seafood (FAO, 2010). A third of the world catch is now used for animal feed and fertilizer, but even if it were simply eaten by people and not fed to livestock, it would maintain present consumption levels per person for only 20 years. Widespread recoveries of wild fish in the face of increasing demand seem unlikely. Improved conservation would have difficulty keeping pace with the population growth. We have likely hit the limit of the oceans' natural capacity to feed us.

Coastal habitat disappears in proportion to population growth, and growth in coastal areas is four times the US national average. Seventy percent of major US cities are located along the coasts, and about half of the human race lives within 120 miles of the sea. Diminished habitat means diminished productivity.

Habitat Issues

Coastal habitat losses are very costly to fisheries. Human alteration of aquatic habitats is a major cause of fishes' declines – the major reason in freshwater, and the second-largest factor (after fishing) in estuarine and continental shelf habitats. Marine habitat is physically altered by development, aquaculture, mining, and fishing activities. Development often causes: extensive filling and diking of critical wetland breeding and nursery areas; dredging to deepen shallow estuaries for shipping; shoreline stabilization; and dams that alter normal

patterns of sedimentation, erosion, and water flow. Dams also block migrations to and from spawning areas, and divert to agriculture, industries, and homes, the freshwater flows needed by wetland and estuarine creatures. Aquaculture often destroys local wetlands and mangrove areas. One-quarter of the world's mangrove forests (about 50,000 square kilometers), for example, have been cleared to free land for food production, often for shrimp culture. Loss of this important nursery habitat has eliminated an estimated 5 million tons of annual wild fish catch, which is about 6% of total world landings. Mining removes coral and minerals, often adding toxic chemicals and sediments that destroy seafloor creatures. Agriculture and deforestation put large amounts of sediments into coastal waters, smothering spawning beds, seagrass flats, and coral reefs. Trawl nets and dredges dragged for fish, clams, and other species extensively damage seafloor structures and living communities. To catch fish from coral reefs, where nets are impractical, fishers often use explosives or cyanide that fragment or poison corals. In the Pacific Northwest of the United States and Canada, intensive deforestation and water diversion destroyed thousands of river miles of salmon spawning and nursery habitat, eliminating hundreds of salmon runs and thousands of related jobs.

Coral reefs support Earth's most diverse fish communities. Coral mining (for construction), fishing with explosives and poisons, destruction from boat anchors and ships running aground, and silt from farms and clear-cut logging cause major damage to coral-dependent communities. Sediment flowing off deforested land is a major threat to coral reefs, killing corals by clogging them, blocking sunlight, and preventing larval settlement.

Introduced Species

Aquaculture, the pet trade, sport fishing, and shipping intentionally and accidentally introduce species to new parts of the world. When ships empty their cargo, they often rebalance by taking on water. In the water are larvae, eggs, living cells, and small animals. When the ships arrive and discharge this ballast water, these hitchhiking species – it is estimated that more than 3000 species are in motion in ships on any given day – may be introduced to a part of the world where they have never existed. Often they arrive without the predators, competitors, or pathogens that limit them at home. Sometimes, organisms are introduced to places where the native species cannot escape or compete with them.

Invasive species greatly alter ecological communities. In San Francisco Bay, a tiny Chinese clam displaced 95% of the bottom community, and now consumes so much plankton that native plankton-eating fishes and, in turn, predatory fish may be affected. In Eastern Europe's Black Sea, introduction of an American jellyfish reduced plankton abundance by 90% in less than a decade, causing small fishes like anchovies to crash. Pacific Lionfish, accidentally released in the early 1990s, have exploded throughout the Caribbean, the Bahamas, and Florida Keys, devouring millions of small fish and changing the community structure of coral reefs. Reef fishes intentionally introduced into Hawaiian waters for sport fishing have affected the local fish communities. The list of examples is long,

and future invasions are inevitable. In one study, five of 80 ships entering Australia carried toxic phytoplankton, which can produce red tides and cause shellfish to become poisonous. Even transporting salmon relatively short distances from one river system to the next for aquaculture or into hatcheries, as often happens, can move diseases into new areas, or expose fish to habitats where they are doomed by diseases for which they have no immunity.

Aquaculture

Many are counting on aquaculture – farming aquatic organisms – to fill the gap between nature's bounty and the hunger of people. Aquaculture is exploding, however. For example, shrimp farming increased 17-fold over the last 25 years, with global value now exceeding \$9 billion annually. Aquaculture now produces almost 50% of humanity's fish. In freshwater, aquaculture exceeds wild catch production by 300% (FAO, 2010). In the oceans, it produces about 40% of shrimp and 80% of salmon in commerce.

Aquaculture does not solve all problems, and causes some new ones. Most saltwater fish farming causes environmental degradation, displaces local people reliant on wild fish and their natural habitats but provides fewer jobs. Aquacultural products are often expensive, and commonly exported to rich countries rather than used locally to ease hunger of the poor people. Crowded fish farming operations pollute by releasing pesticides, antibiotics, and oxygen-robbing feed and feces into semi-enclosed waterways. Shrimp farming has a record of boom and bust caused by pollution and disease outbreaks. In Asia, shrimp ponds rarely remain viable for more than 5–10 years before being abandoned because of contamination (Naylor *et al.*, 1998). Thousands of Atlantic salmon have escaped in the Pacific Northwest. The state of Washington listed the Atlantic salmon as a pollutant because of its potential to cause problems for the several native Pacific species of salmon. Atlantic salmon have been discovered breeding in the wild in British Columbia. Even in the Atlantic, escaped Atlantic farmed salmon interbreeding with wild salmon cause genetic degradation, because wild salmon are genetically finely adapted to characteristics in the specific rivers where they spawn. Moreover, ponds and other open systems attract wild fish-eating birds such as cormorants and herons, often bringing them in range of farmers' guns.

Most importantly, most aquaculture consumes vast quantities of wild fish as feed – and is thus a net loss of food from the oceans. Most believe that aquaculture contributes to the supply of human food, and this is true for the few herbivorous species. But fish are not cabbages; they do not grow on sunlight. Most fish and shrimp are carnivorous, and feeding them uses two to four times as much wild fish as the farms produce. Farming such species actually contributes to the ocean's depletion.

Aquaculture does not take pressure off the seas. Wild larvae of species that do not breed in captivity are sometimes intensively caught for pen-rearing. Increased shrimp and salmon farming has not lessened fishing intensity even for those species, and has brought trouble to wild shrimp and salmon through diseases and habitat destruction.

Aquaculture can be done responsibly but as usually done now it destroys naturally productive habitats that support ocean fisheries and wild communities, and introduces alien

species, parasites, and diseases that threaten local species' populations. To be responsible, aquaculture enterprises should not be sited where natural habitat is affected, their wastewater should be treated, and they should focus on plant-eating species, raised in closed systems to prevent escape.

Pollutants

Pollution is the introduction of substances in quantities that are threatening to living resources and human health and activities. Chemical pollution can cause spectacular mass mortalities or cause subtle changes in population composition, impaired sexual development and reproductive success, impaired growth rates, deteriorated seafood quality, tumors and other diseases, and outbreaks of harmful algal blooms such as red tides, *Pfiesteria*, or normally innocuous algae that overgrow corals or deplete waters of oxygen. Chemical pollutants tend to concentrate in surface waters, where larvae and eggs also concentrate. Chemicals enter the seas from sewage, industrial outfall, agricultural runoff, ocean dumping, aquaculture, accidental spills, and from the air (acid rain has significantly damaged freshwater fishes in North America and Europe). Major chemical pollutants include insecticides and herbicides, detergents, PCBs, elements such as chlorine and heavy metals, petroleum products (much of the gasoline/oil mixture run through 2-cycle outboard engines exits unburned), mining wastes, fuel ash, radioactive materials, and excessive nutrients from sewage, farm animals, and fertilizers.

When algal blooms caused by excessive nutrients use up those nutrients and die, their subsequent decomposition can rob the water of oxygen, suffocating marine creatures. The surprising fact that fertilizer or other nutrients in excessive amounts can kill aquatic organisms is sometimes called "the paradox of enrichment."

About three-quarters of marine pollution comes from the land, thus the people causing the pollution do not feel its effects directly or immediately, and the people feeling it (e.g., fishers) cannot directly affect its origin. Spreading from the mouth of the Mississippi River, nutrient runoff from farm land produces a dead zone greater than 20,000 square kilometers in some years, reducing oxygen concentrations to dangerous levels and affecting important shrimp and oyster fisheries. Over the long term, this is more a threat to the Gulf than the spectacular Deepwater Horizon oil blowout of 2010. New York City's harbor gets more than 27 billion gallons of storm-water, which includes raw sewage, every year. That is one reason why laws are necessary. In the US clean water legislation has helped keep some fisheries economically viable by controlling pollutants.

Global Atmospheric Change and Fish Conservation

Major atmospheric changes, like global warming and rising CO₂ levels, have significant implications on marine life. Earth's climate has changed dramatically as ice ages have come and gone, but these changes took many thousands of years, allowing life-forms long periods in which to adapt. Human-caused climate change is happening much faster, and some

habitats and species will probably not change or move fast enough to survive.

The burning of fossil fuels has increased atmospheric levels of carbon dioxide, methane, and other heat-trapping gases, and most scientists agree that this is intensifying the greenhouse effect, the warming of Earth's atmosphere. Oceans slow the buildup of greenhouse gases by absorbing about a third of the carbon produced by burning, but substantial climate change is likely over the next few decades. The effects of such changes are not straightforward, but planetary warming is melting polar ice caps; causing population declines in ice-dependent krill, the shrimplike key prey species for Antarctic fishes, marine mammals, penguins, and other seabirds; causing changes in the distribution of many temperate species; and raising sea levels throughout the world. This rise is expected to cause some flooding and loss to coastal marshes, mangrove areas, low-lying islands, and their critical associated fish-nursery habitats, as well as to some cities. Global warming is directly affecting fish abundances and forcing latitudinal migrations of some populations. The Atlantic Cod population in the North Sea is moving northwards, while Cod populations in the Celtic and Irish Seas will likely disappear by 2100.

Warming is likely to alter ocean currents. Such changes may intensify the recurrent El Niño phenomenon. Other possible changes include alteration of currents such as the Gulf Stream and Kuroshio Current, and weakening of major upwellings off South America and Africa. Such changes would affect the production, distribution, and survival of fishes and other creatures in the world's oceans, and alter the fish availability among countries.

Changing sea temperatures will exert major influence on the survival and distribution of the oceanic populations. In parts of the California Current, planktonic animals declined 70% over the last 40 years, a decline many scientists think may be linked to global warming.

Our addition to fossil fuels is also driving ocean pH to dangerous levels. Our oceans absorb 22 million tons of carbon dioxide (CO₂) daily, much from industrial processes, which when dissolved in seawater forms carbonic acid in a process called "ocean acidification." Ocean pH has dropped from a preindustrial value of 8.18 to 8.07 today, and is expected to reach 7.82 by 2100 (Orr *et al.*, 2005). pH is measured on a logarithmic scale, so a 0.1 decrease means our oceans are 30% more acidic today than 250 years ago. This is having a dramatic and wide ranging impact on fish populations and marine ecosystems. For some fish species, increasing acidity decreases larval survival and replenishment of reef fishes, interferes with their olfactory system so they do not flee predators, and reduces growth. Ocean acidification is reducing survival and growth of organisms low on the food chain, with potentially severe ripple-effects through the entire food web.

Some ecosystems may simply dissolve. Coral reefs, made from the calcium carbonate (CaCO₃) skeletons of corals and coralline algae, require waters super-saturated in aragonite (one form of CaCO₃) to exist and grow. While more than 98% of coral reefs were bathed in aragonite-saturated waters before the industrial revolution, ocean acidification has already put 40% of reefs into unfavorable conditions (Cao and Caldeira, 2008). If CO₂ levels increase as predicted, by 2050 aragonite levels will be too low to support the formation of coral reefs

anywhere. At this stage, coral reefs will stop growing, and start dissolving. All coral reef organisms including the 4000 species of fish that feed on and live in this fragile ecosystem will lose their habitat. Loss of coral reefs will directly affect about 100 countries and territories that rely on them for fisheries, tourism, and coastal protection.

Certain human-generated compounds such as chlorofluorocarbons rise into the stratosphere and destroy the ozone that shields Earth from the sun's ultraviolet radiation (UV). The biologically damaging UV is called UV-B, and it penetrates many meters below the sea surface. It has increased under the Antarctic ozone hole and elsewhere. Also, recent volcanic eruptions have reduced total atmospheric ozone by as much as 10%, leading to increased UV-B of up to 20% in latitudes as far from the poles as Florida and the Bahamas. This has caused significant damage to plankton (small drifting animals and plants, including fish eggs and fish larvae), corals, and bottom-living organisms. Controls on manufacture of chlorofluorocarbons have stabilized this situation and scientists predict recovery of ozone densities later in this century.

Marine Fish Conservation in a Biodiversity Context

Biodiversity is the diversity of living things, and can be thought of as occurring on three levels: genetic diversity, which is the genetic variability among members of the same species; species diversity, the variety of species found in a community or an ecosystem; and community diversity, the varieties of biological communities on Earth. We will use these categories to examine the fish conservation issues introduced above.

Marine Fish Biodiversity

The greater the diversity of habitats, and the more isolated habitats are from each other, the greater is the diversity of species adapted to those habitats. (Though freshwater covers only 1% of Earth and ocean fish populations are vastly larger, 40% of the world's fish species live in freshwaters because they are so isolated from each other that they evolve differently.) Because most ocean habitat diversity is coastal, so is most ocean fish diversity – there may be 10 times as many coastal fish species (roughly 13,000) as truly open-ocean fishes (about 1200 species).

Genetic Diversity within Species

Conservation of biodiversity is virtually never an official management goal in fisheries. (Indeed, if we wanted to try to exterminate the fish, we could hardly have gone about it differently than we have gone about fishing.)

Fishing can induce genetic changes through unintentional selective breeding because of intensive, nonrandom fishing mortality. In intentional artificial selection (as for farm animals) we choose and breed individuals with traits that we desire. But in fishing, we remove from the breeding population those individuals with the traits we desire.

Fishing activities can cause evolution (Sutherland, 1990). Evolution is a change in the relative frequency of genes. It need

not result in progress or new species; it merely shapes species for better survival under prevailing, often changing, conditions (if change is extensive, new species can result). Fishing is so intense in so many places that many fishes have a higher chance of dying by being caught by people than by natural causes (for instance, in some populations 80–90% of adult cod or salmon are killed by fishing).

Fishing can alter inherited characteristics of a population in two ways: (1) by applying a selective pressure that kills individuals based on certain traits, such as size or age; and (2) by applying a random pressure so intense that the population is depleted low enough to lose genes from the pool. Note that fishing can do these things, and it does both of them sometimes, but not all fishing results in genetic changes; whether it does is determined by fishing intensity.

Genes related to size, growth rate, and age of sexual maturity are most likely to be affected by fishing (Sutherland, 1990). Growth overfishing prevents fish from reaching large size, thus it incidentally results in populations of fish genetically preprogrammed to mature and breed younger and at a smaller size than was normal in the absence of fishing pressure. Fish that reproduce pass their genes on. The genes of fish that get killed before breeding will begin dying out. Fish genetically programmed to breed at a slightly younger age than average are also likely to be fish programmed to be smaller as adults. Thus, intense fishing that allows few individuals to live longer will cause normally maturing fish to make a disproportionately small contribution to the next generation, and allow early-maturing fish to make a disproportionately large contribution. In a study modeling the contribution of three age groupings of cod to overall reproduction, the late-maturing subgroup made virtually no contribution to reproduction after only 7 years of intense fishing. This process likely operates on wild populations subject to intense fishing. So fishing can unintentionally breed a population of younger-reproducing, shorter-lived, smaller fish.

Intensive fisheries probably create conditions necessary for genetic change, but genetic changes can be difficult to confirm. Reduced average sizes and younger ages at first breeding do not necessarily reflect accompanying genetic change. They can result from changes in densities and competition for food, too. Whether genetic or not, examples abound of population-level effects of overfishing. In a rock fish (*Sebastes alutus*), lightly exploited populations had a modal age of 30 years, and 73% of the fish were over the age of 20; heavily exploited populations had a modal age of 12 years, with only 7% of the fish over the age 20.

Average sizes of many US Southeast species declined about 75% between the early 1970s and the mid-1980s: red porgies went from 2.6 pounds to 1.3 pounds, red snapper from 18.0 to 4.4 pounds, snowy grouper from 17.6 to 4.4 pounds, speckled hind from 19.1 to 6.6 pounds, scamp from 10.1 to 3.3 pounds, and gag grouper from 18.0 to 4.4 pounds. For species such as groupers, which change sex in older age, intense removal of larger individuals can dramatically affect sex ratios and mate supply, greatly lowering the population's reproduction. Jim Bohnsack of the National Marine Fisheries Service has said that if almost all the big ones are taken and the little ones left, "The result is a race of miniatures."

Overfishing reduced the California sardine population's age structure from five spawning age classes to only two, and

two consecutive years of poor oceanic conditions led to spawning failure and collapse. However, even when vast populations of naturally small, short-lived fishes such as sardines, anchovies, and herrings collapsed to one-thousandth of their former numbers, high enough numbers have remained to maintain genetic diversity. Yet in some animal populations, older or larger individuals are more likely to carry more diversity in the form of heterozygosity – differing forms of particular genes. Larger individuals often spend more time on breeding areas than younger ones, so fisheries targeting spawning groups, such as those for groupers, orange roughy, and many others, can subject the most genetically diverse individuals to the most intense mortality. This kind of genetic diversity loss is believed by some to be a common consequence of heavy exploitation, even without reducing populations to near-extinction levels.

Theory suggests that genetic change from fishing is likely to be common, and several studies have found convincing evidence. Perhaps the species best-studied before and after commercial exploitation is a long-lived fish called the orange roughy. Off New Zealand, only 6 years of heavy commercial exploitation reduced populations by 70% and significantly reduced genetic diversity within those populations, probably because older individuals in this very long-lived species were more heterozygous. In one North Sea cod population, intensive fishing reduced the chances of a young cod surviving to breeding age by 95%. Over several decades, average age of sexual maturation declined from about 10 to 7–8 years, apparently through genetic change. Some populations of flounder and haddock also show convincing evidence of genetic change. In a population of Atlantic salmon, average age at maturity had dropped after two decades of heavy fishing. In a study of chinook salmon, average spawning age fell by 2 years. Other studies on salmon showed other changes. In sum, some studies found no apparent changes attributable to fishing, some showed changes that were inconclusively genetic, and other studies showed genetic changes that were driven by intense fishing.

Species Diversity

Human activities significantly change species composition and abundance, and predator–prey and competitive relationships. Naturally evolved numerical and functional relationships among species are sometimes referred to as the community's ecological integrity.

One indication that many regions' ecological integrity has greatly diminished is the changing world catch. Since 1950, many fisheries, forced to work lower on the food chain as they deplete large fish, have shown a gradual transition from catching mostly large, long-lived, fish-eating bottomfish such as cod toward catching small, plankton-eating, open-ocean fishes like herring, as well as short-lived, low-on-the-food-chain invertebrates like squid (Pauly *et al.*, 1998). Daniel Pauly, the eminent ecologist who helped discover this trend, remarked, "If things go unchecked, we might end up with a marine junkyard dominated by plankton."

Various marine communities have been changed by overfishing. A common pattern – particularly acute in coral reef systems but also seen in kelp communities and elsewhere – is

selective removal of the largest species first, then of large individuals of smaller species. People removed most large groupers and sea basses from many coral reefs and kelp forests, and manatees, dugongs, and sea turtles from seagrass communities, before scientists ever studied these habitats. Though no one really understands how those communities are evolved to function, they were certainly very different. Since Columbus landed in the Bahamas, for instance, Caribbean sea turtle populations have declined 99% (Jackson, 1997).

Depletion of fish populations changes patterns of abundance, distribution, and competition among plants, urchins, corals, sponges, tunicates, and other creatures. Alarming declines in North Pacific seabirds, Steller's sea lions, and other wildlife may be caused by heavy fishing. When fishing depleted Barents Sea herring and capelin, cod failed for lack of food. Squid sometimes increase following the collapse of their overfished predators. Off New England and maritime Canada, overfishing shifted communities dominated by cod, haddock, and flounder to domination by spiny dogfish (a small shark) and skates (a type of ray). But not even skates are safe. Fishing has driven the commonest skate in the northeast Atlantic, *Raja batis*, to local extinction in the Irish Sea.

Vulnerability of Marine Fishes to Extinction

Few fully marine creatures, and perhaps no fully marine fish species, have gone extinct because of human activities. Many marine fishes have large distributions and a greater chance for replacement by neighboring populations if they are locally wiped out. But the important thing is to prevent, not document, endangerment and extinctions. The time to save a species is when it is still common. Waiting until biodiversity declines, until populations falter, and until more species names get added to various endangered lists will only ensure three things: (1) more species will get into serious trouble, (2) the value to humanity from extremely important natural resources such as fishes will be seriously diminished, creating more of the economic, social, and nutritional problems already suffered by people in too many communities throughout the world, and (3) fixing the problems will be much harder, more expensive, and prone to failure.

Numerous fish have already been listed on the U.S. Endangered Species List, on the U.S. Overfished Species List, and under the world Convention on International Trade in Endangered Species (CITES) and the World Conservation Union's Red List. The Red List notes that hundreds of marine fish have suffered major and rapid population declines or significant local extinctions (extirpations). Most vulnerable are those that breed in freshwater but mature in salt water – the anadromous species – such as salmon and sturgeons, because they suffer overfishing plus the effects of habitat disruption in rivers that are heavily dammed, subject to intensive agricultural water withdrawals, or subject to massive siltation from destructive logging practices. Hundreds of North American salmon runs are already extinct, and the trends for sturgeons and totoaba (a large fish of the croaker family that is dependent on Colorado River flow into the Gulf of California) suggest that biological extinction may become a real possibility. Groupers are also vulnerable; they are generally slow-growing fishes whose spawning groups are easily targeted by

fishers. Long-lived, slowly reproducing species such as large sharks and sawfishes are particularly vulnerable, and many such species are now depleted and threatened. Several large sharks, including the great white, are now totally protected in some regions, an acknowledgment of their threatened status.

No doubt endangerment to fishes is underappreciated simply because their populations are not well studied. Most of the 300-plus species listed on the World Conservation Union's Red List got there simply because the London Zoological Society and World Wide Fund for Nature convened a workshop to compare known information about fish population changes against the Union's listing criteria. Similarly, the barndoor skate became endangered without anyone realizing it, simply because no one had analyzed decades of already-existing data.

Not just fish are affected. Wild abalone populations off California have been greatly reduced by fishing, and the white abalone is almost certain to go extinct in the wild because probably too few individuals are left to breed effectively. Who would have thought that fishing would be intense enough to drive a snail to extinction?

Kinds of Extinction

Overfishing and habitat degradation can lead to a four-step process of extinction, in which people suffer the major effects long before the last animals vanish. From social, economic, and genetic standpoints, extinction is a process rather than an event; fishing economies usually go extinct and gene pools lose diversity long before the last fish dies.

The first stage of the extinction process is depletion, wherein the fish population is reduced below its most productive level; fish are smaller and fewer than they could be, and less likely to spawn a strong year class of young fish. Consequently, the population's ability to support fishing is reduced, and profit margins decline. Other members of the ecosystem may experience food shortages or an unnatural relaxation of predation pressure or competition.

The next stage is ecological extinction, where the animal's population drops so low that the species no longer effectively functions as prey, predator, or competitor in the community. If it is an important keystone species affecting many others, entire marine communities may undergo profound shifts in numerical and functional relationships, and species less valued by people may increase. Animals that have become ecologically extinct – essentially removed – from the southern California kelp community, for example, include sea otters, black sea bass, white sea bass (though it has been recovering), large groupers, all the large kelp bass, sheephead, rays, flatfish, rock fish, lobsters, abalones, sea urchins, sea cucumbers, and others.

Another stage, commercial extinction, occurs when the species becomes too rare to be fished profitably. During this phase, fishery managers sometimes close large areas to fishing, as off New England and Newfoundland, or in the salmon fisheries off the Pacific US coast.

If commercial and ecological extinction are not reversed, total extinction may become a possibility. But by the time total extinction becomes an issue, all the other practical effects of the creature's disappearance from commerce and from the ecosystem have already been suffered by people. One cannot ignore the community effects of overfishing on the top predators – humans. Through dislocation, malnutrition in

remote local villages, job loss, and loss of social identity, humans suffer the major effects of overfishing long before the animals themselves completely vanish.

To date, total extinctions are rare in the oceans, but this may not always remain so. We may unfortunately see more fish on endangered species lists in the future. If we do, it may not be too late to save them. But it will likely be too late to save the fishing jobs and coastal communities that once depended on them. A recovery vision should always include regaining the numerical and functional relationships that had naturally evolved among species.

Ecosystem Diversity and Fishes

Though the ocean may seem like one big bathtub, to the creatures in it and the people making a living from it, the sea is more like a mosaic of habitat types. Water circulation patterns can create discrete habitats because temperature alone can be a boundary for sea life. Currents also cause drifting seaweeds to accumulate in places like the Sargasso Sea, an area in the middle of the Atlantic characterized by vast mats of sargassum weed used as habitat by many creatures. The sediments of the seafloor vary in texture, from boulders to fine silt and clay, all creating different habitats. The area between high and low tides – the intertidal zone – likewise contains particular habitats for specially adapted creatures that live on rocks, in sand, or in tide pools. Along coasts, shallow estuaries, where freshwater from rivers mixes with salty seawater, have their own suite of habitats: seagrass flats, salt marshes, bays between outer beaches and mainlands, and tidal inlets. Tropical and subtropical shores often support mangrove forests growing in salt or brackish water. Near warm shorelines, coral reefs support the most spectacular diversity of fishes and other creatures in the sea.

The distribution pattern of these major habitat types is what we speak of with the term ecosystem diversity. Just as fishery management has generally ignored genetics, it has also generally ignored ecosystem considerations. Fishing activities, aquaculture, coastal development (for instance, damming rivers and filling wetlands), and atmospheric warming have resulted in changes in the distribution and functioning of habitats on which marine communities rely – that is, changes in ecosystem diversity.

Aquaculture has significantly altered coastal and estuarine habitats in many parts of the world. The conversion of mangrove habitats into fish and shrimp farms over extensive areas is a form of ecosystem depletion. Coastal development has also destroyed habitat in ecologically significant areas. For instance, about half of the wetlands in the US have been lost to practices like filling, which has led to a significant shift in the distribution of aquatic habitats. Atmospheric warming is both melting Antarctic ice and stressing coral reefs. This is causing change in these habitats on a global scale.

Coral reefs and continental shelves are two major kinds of habitats experiencing profound changes due to human activities. Small increases in temperatures in tropical seas cause coral bleaching, whereby corals lose the helpful algal cells living inside them, turn white, and die. Rates of coral bleaching also increase with decreasing pH, thus the combined effects of global warming and ocean acidification will

damage all reef corals to some degree. Widespread death of corals, of course, has potentially severe implications for coral-dependent fish and human communities.

Coral reefs are the oldest and largest structures built by living things. When scientists first surveyed them in the 1950s and 1960s, most coral reefs were poised on the edge of profound change in the composition and abundance of species and the functioning of coral reef communities. For example, Caribbean overfishing had already depleted herbivorous fishes to very low levels when algae-eating sea urchins crashed from a disease (Roberts, 1995). Without herbivores, algae overgrew corals, killing them over large areas, and altering the community. Conversely, heavy fishing off East Africa depleted fish that prey on coral-eating sea urchins. With their predators largely fished-out, the urchin populations exploded to densities that were 100 times the normal, and proceeded to inflict significant damage to reefs. The depletion of predator fishes has also been implicated in destructive outbreaks of the coral-eating sea star known as the crown-of-thorns. Such ecological changes affect large communities of organisms.

Fishing often kills corals directly when people use explosives to kill fish, or pound the coral with rocks tied to lines to scare fish toward nets, or use cyanide to stun fishes. All of these methods cause extensive destruction of coral reefs, through either breakage or, in the case of cyanide, death to corals by poisoning.

Coral reef systems are perhaps more sensitive to environmental change than most other marine ecosystems. For various reasons, species of algae may overtake a damaged reef preventing corals from recovering or recolonizing. Many coral reefs are now degraded by human activities, their fish communities modified, and the living corals replaced by algae growing on dead corals. The Caribbean region has lost 80% of its live coral since the 1970s because of overfishing, diseases, algal overgrowth, sewage overfertilization, and smothering silt running off deforested land areas. Some scientists believe these changes may be very long-lasting.

Aside from coral reef areas, continental shelves nearly everywhere are affected by bottom trawling – the towing of large bag-shaped nets or shellfish dredges over the seafloor. Trawling is the fishing method that takes half of the world catch. The vast majority of the world's seabed is encrusted or honeycombed by living things, and trawling causes enough incidental damage of nontarget invertebrates, plants, shellfishes, and fishes to cause major community changes over large areas. Trawling crushes, kills, exposes, and removes these living sources of nourishment and hiding places, making life dangerous for young fishes and almost certainly lowering the habitat's capacity to produce abundant fish populations. In one study of a scallop fishery, only 12% of the scallops in an area were actually caught, but many of those not caught were crushed by scallop dredges.

Until recently, trawlers were unable to work on high-relief, bouldery, or rubble-strewn bottom habitats without risking hanging up and losing their nets and gear. But nowadays, new kinds of trawls make every kind of seabed – whether silt, sand, clay, gravel, cobble, boulder, rock reef, worm reef, mussel bed, seagrass flat, sponge bottom, or coral reef – vulnerable to trawling. Furthermore, trawls hit many areas repeatedly each year. The seafloor structures that juvenile fishes rely on are

often easily destroyed by bottom trawls, which kill or disperse the organisms that create those structures. Our focus on extracting edible fishes at all costs has effectively blinded fishery managers to the essential food and shelter that these fish themselves require. Trawling is not uniformly bad for all species or all bottom habitats, and in fact some species do better in trawled than in undisturbed habitats (just as a few species do better in logging clear-cut areas). But most species are not helped by trawling, and some communities are seriously damaged. Recovery of certain bottom communities could require up to a century even if trawling was stopped today. Writing in the journal *Nature*, Daniel Pauly and Villy Christensen observed that, "Contrary to some terrestrial systems such as rainforests, of which large undisturbed tracts still exist,... the overwhelming bulk of the world's trawlable shelves are impacted by fishing, leaving few sanctuaries where biomasses and biodiversity remain high."

The Course Ahead

Marine Protected Areas

In times past, fisheries benefited from *de facto* refuges: undiscovered locations or places too deep or remote to probe. But now, because of new technologies, when fish run they cannot hide. Facing this reality, some scientists have proposed that simply closing some areas to fishing and resource extraction, to allow them to function naturally, while leaving adjacent areas open, is the best way to manage fishing. These closed areas have been suggested especially where precise estimates on population sizes and sustainable catch levels are lacking and where gathering lots of data or intensive management and monitoring are impractical.

Such marine reserves allow fish to go through their normal patterns of growth, abundance, reproduction, genetic diversity, and community structure. Marine reserves can (1) protect critical spawning adults, (2) maintain natural size and age structure, (3) maintain genetic diversity, (4) prevent serial overfishing, where one species and then the next and the next are depleted, (5) maintain natural communities, while allowing fishing to continue nearby, and (6) provide scientific areas for the study of more naturally functioning systems (Norse, 1993). A global review (Halpern, 2003) of marine protected areas (MPA) determined that within reserves, fish sizes are 30% larger, densities are double, and biomass levels are triple compared with unprotected areas. Over 5000 MPAs exist, but they cover less than 1% of the world's ocean. And even in many reserves, fishing is allowed. Fishing, for example, is allowed in all US National Marine Sanctuaries. Marine reserves have been established in several parts of the world, and as populations recover, fish reach their normally evolved maximum size, and their offspring begin wandering outside the reserve, they can increase fish yields in adjacent areas. In the Philippines, catches adjacent to one reserve tripled within two years of the reserve's designation. In a small Caribbean reserve, overall biomass of commercially important species increased 60% and snappers increased 220% in two years; but groupers did not increase, probably because severe depletion eliminated any source of larvae.

Eggs and larvae of fishes and other marine creatures may drift many miles from their source, so reserves must either be self-sustaining sources of fish or areas where incoming juveniles can grow and reproduce. Ideally, reserve networks should be designed to maintain genetic and community diversity over large regional areas. Large adults are disproportionately fecund – a single female red snapper 24 in (61 cm) long produces as many eggs (about 9 million) as *two hundred* 16-inch (41 cm) females (Bohnsack 1996). One study estimated that if 20% of the red snapper's Gulf of Mexico habitat was protected, total egg production would be 1200% greater than under current fishing pressure. Total fish catch would increase even though a fifth of the area was off-limits to fishing. For more migratory fish, seasonal and area closures of areas such as spawning and nursery grounds could be helpful. For example, longlines catch mostly immature swordfish in certain areas. Those areas should be closed to long-lining during times where breeders or juvenile fish concentrate. Reserves are generally opposed by fishers at first, but in New Zealand they worked so well that 10 years after their establishment nearly 80% of fishers wanted more reserves.

Other Solutions, and Reasons for Optimism

The current situation is poor, but not bleak. There are reasons for optimism. For one, we know enough about many human-induced problems, especially overfishing and habitat alteration, to fix them. Clearly one of the most important things that could be done for overfishing and bycatch is to remove the artificial tax breaks, supports, and all the other subsidies that are propping up fisheries incapable of existing off the resources. And many fishes (though not sharks) have high reproductive potential and may be able to repopulate relatively quickly if fishing and habitat degradation are controlled. Where this has been done, protected populations have often shown the ability to increase rapidly.

Some areas should be closed to trawling even if left open to stationary fishing gear such as traps or hook-and-line, which do not destroy the habitat. New Zealand and Australia have

closed areas to bottom trawling, as have some US states. Trawls should be allowed on shallow sandy bottoms that are relatively resistant to disturbance, and barred from harder, higher-relief, and deeper bottoms where their damage is much more serious. Government and industry should create incentives for developing fishing gear that does not degrade the very habitat on which the fishing communities depend. Intelligently designed financial incentives for encouraging new problem-solving technology could tap fishers' inherent inventiveness in constructive ways. Reducing the problems of species introductions will require methods for safely sterilizing ship ballast water, and controlling aquacultural movements of species and their hitchhikers and pathogens.

Public interest and commitment regarding the oceans are much higher in just the last few years than ever before, and conservationists have discovered that fish are wildlife. Consumers hold tremendous power to direct change, but they have hardly been informed about how they can "vote with their wallets" in the marketplace to favor sustainable fishing. Initiatives like the Blue Ocean Institute's seafood guides and the Marine Stewardship Council (fishery certification program wherein participating seafood producers receive an on-pack logo saying this product is sustainably produced) help empower consumers. Much more can be done in this area.

Many discussions of fisheries highlight the need for more information in order to manage wisely. But one does not need to fully understand ecosystems to limit obviously detrimental human behavior. Most of what limits our ability to manage is political resistance and lack of enforcement – better knowledge will not necessarily lead to better management (see Box 6). Reducing the undue influence of the irresponsible segments of the fishing industry in management arenas, and their incessant political pressure to allow higher and unsustainable catches, is a necessary first step.

Fish Conservation

At present, in almost all parts of the marine realm, exploitation reigns and conservation begs indulgence. The burden

Box 6 Smuggling Whales

Though whales are mammals, not fishes, whaling is sometimes considered a fishery and is similar to fishing in many aspects. Originally, whales were hunted for their meat, but during the seventeenth century commercial whaling focused on another product: whale oil. For over 200 years, more than 50,000 whales were caught annually, driving many species like the blue whale and North Atlantic right whale to near extinction. In 1986, the International Whaling Commission banned commercial whaling, but whaling to supply meat still occurs in several countries for traditional purposes by indigenous tribes, or under the guise of "scientific whaling" and other loopholes.

Japan kills hundreds of minke, fin, and humpback whales in Antarctic waters each year, ostensibly for scientific purposes. But the samples go to food markets, and the markets serve as continued incentive to hunt whales illegally. Iceland and Norway kill hundreds of minke and fin whales in northern waters annually, with the meat eaten locally or exported to Japan.

The export or international trade of whales is prohibited by Convention on International Trade in Endangered Species (CITES), but Japan, Iceland, and Norway maintain reservations on the CITES treaty for whales, essentially a loop-hole to allow trade of whale meat. Whale meat cannot be legally traded with other countries, but a recent study found that whale meat was available for purchase in the USA and South Korea (Baker *et al.*, 2010). Sometimes whale meat is mislabeled, listed as the more common "minke whale" when it is really from endangered species like fin and sei whales. Falsifying catch records is problematic in commercial whaling, with the Soviet Union underreporting 100,000 whales caught in the Southern Hemisphere prior to the 1970s. This dishonesty is why the arguments about sustainable hunting of whales are flawed and sometimes fraudulent, and why any whaling may prevent recovery of endangered whales in the vast areas of the world's oceans where they are still vanishingly rare.

The Atlantic gray whale was apparently hunted to extinction, but whales stand a good chance of recovery when effectively protected. This has been proven by increases of several great whale species in the Northwest Atlantic, humpbacks that breed in Hawaii, blue whales off California, and the recent full recovery of the Pacific gray whale – one of the great successes of the U.S. Endangered Species Act.

of proof must shift, so that conservation and restoration are the rules and exploitation becomes an effectively regulated privilege. Otherwise, the kingdom of the sea will sink deeper into poverty, creating more and more problems and hunger along the world's increasingly crowded coasts. Of course, human overpopulation and overconsumption drive or worsen each of the problems discussed here.

Anyone interested in conservation can join organizations working in this area, write letters to agencies and government officials, speak at meetings and hearings, and write opinion pieces and letters to editors of various publications. Making your voice heard is the most important thing. Public education is vital in conserving fish populations, and today there are many services, from wallet guides to cell phone applications and texting products, that provide instant information about the health of a seafood species or the environmental impact of catching them.

The solutions to overfishing and marine habitat destruction depend on political will, but politics reflects public opinion, and that means politics can be changed. Already, because of changing political "seascapes," several formerly unlikely long shots have been achieved – including the global ban on drift netting, strengthening of US fisheries law toward ending overfishing and hastening the rebuilding of depleted populations, several new international fishing treaties and agreements, and increasing the acceptance of the "precautionary principle" that says we should act conservatively, consider future needs, and so avoid irreversible change. Only by increasing our political involvement and effectiveness will we be able to improve the ecological health and protect the biodiversity of the world's oceans. Conservation itself is a political activity in the service of living nature.

Glossary

Biomass Collective weight or mass of all the members of a given population or stock at a given time, or, on the average, over a certain time period.

Bioquads Occurrence record of organisms, serving as key units for biodiversity research and consisting of four elements (species names, location, time, and source).

Catches The fish (or other aquatic organisms) of a given stock killed during a certain period by the operation of fishing gear. This definition implies that fish not landed, that is, discarded at sea, or killed by lost gear (ghost fishing), should be counted as part of the catch of a fishery.

Ecosystem Area where a set of species interact in characteristic fashion, and generate among them biomass

flows that are stronger than those linking that area to adjacent ones.

Recruitment Entry of juvenile fish into the (adult) stock. Recruitment is distinguished from reproduction, because the eggs and larvae that result from fish spawning usually suffer tremendous and largely unpredictable mortalities, thus uncoupling spawning from recruitment.

Trophic level A number indicating the position of a species within an ecosystem through the number of steps linking it to the plants. By definition, plants are TL = 1, herbivores are TL = 2, and so on. Note that trophic levels do not need to be whole numbers; intermediate values occur among omnivorous consumers.

The major adaptations of fishes which determine their spatial distribution pertain to their specific anatomy, reproductive biology, and respiratory physiology. Further, fishing has become increasingly important to the biodiversity of fish, either through its direct impacts (changes of stock size and age structure, and overall biomass reductions, down to extirpation of populations), or by modifying the ecosystems in which fish are embedded. Research on biodiversity of fish (or other organisms) must interpret the huge amount of error-prone observational data in the context of the environmental preferences of the species and of their known native range. Management regimes aiming at preserving fish biodiversity at the level of species, populations, and genes, will have to include much stricter regulation of fishing and the establishment of no-take areas.

Major Adaptations of Fishes

Anatomy and Physiology

With about 32,000 recognized species in over 500 families, fish are the most diverse vertebrate group. However, their watery habitat, while failing to protect them from modern fishing gear, makes it difficult to fully appreciate this diversity, and the extent to which it is now threatened. It is even more difficult for us, as air breathers, to perceive the constraints under which fish, as water breathers, were forced to evolve.

Water is an extremely dense medium, 775 times heavier and 55 times more viscous than air. Further, water contains 30 times less oxygen than air, and this oxygen diffuses 300,000 times more slowly than in air. These physical constraints, which shaped all early life forms, including the jawless predecessors of the fish, the agnathans, are best visualized by describing the major evolutionary trends leading from agnathans to modern fish (Figure 1(a)).

The first of these trends was the evolution of jaws from the first upper and lower gill arches of agnathans. This built on the intimate connection, in the most primitive vertebrates, between the feeding apparatus (i.e., the mouth) and the respiratory apparatus (i.e., the gills adjacent to slits on both sides of the anterior part of the alimentary canal). Water-breathing invertebrates lack this close connection between feeding and breathing, one possible reason why even the largest among them (giant squids) cannot reach the mass of the largest fish (34 metric tons, for the whale shark *Rhincodon typus*).

The reorganization of the head of early fish allowed larger gills to evolve, which allowed the higher metabolic rates required for swimming in open waters. This transition was assisted by the gradual loss of the heavy armor protecting the slow, bottom-slurping agnathans. The fine teeth covering the bodies of sharks are vestiges of this armor.

Fast swimming in open water required better fins, both for propulsion and for steering. Propulsion is provided in most fish by oscillations of a caudal fin whose aspect ratio (Figure 1(c)) gradually increased toward tunas and other derived, fast-swimming groups with very large gills. Steering, however, is provided by dorsal, pectoral, and anal fins. These fins are stiffened for precise action by hard, bony rays in the most derived fish, the teleosts, whose evolutionary success was further enhanced by a complexly built protrusile mouth that enables capture of a wide range of food items (Figure 1(b)).

Subtle anatomical changes in fish can thus create more niches for increasing the numbers of specialists, which then occupy increasing numbers of closely packed niches. Ecosystems in which these changes have run for long periods, undisturbed by physical changes, therefore contain very large numbers of fish species. Their numbers are even larger in areas such as the Great Lakes of Africa and the tropical Indo-Pacific, where changes of water levels have repeatedly isolated basins

Figure 1 Major evolutionary trends from agnathans to extant fishes. (Note that no direct ancestor–descendant relationships are implied among the groups depicted.) (A) Trends toward larger gills; (B) trends toward efficient jaws; (C) trends toward effective paired and unpaired fins. (Note the aspect ratio of the caudal fin, defined by $A = h^2/s$, where h is the height and s the surface (in black) of the caudal fin, and of which high values define fast, large-gilled continuous swimmers, and conversely for low values.)

and subpopulations, thereby accelerating species differentiation (Figure 2).

Reproduction and Recruitment

Though many ancient fishes such as sharks and rays or the coelacanth *Latimeria chalumnae* practice internal fertilization and produce few large eggs or live offspring, more recently evolved fishes produce numerous small eggs that are fertilized externally and develop as part of the plankton, without parental care. The larvae that emerge from these eggs, after less than one day in warm tropical waters and up to two weeks (and more for larger eggs in cold temperate waters) are usually elongated, as befit small, finless zooplankton feeders.

The average zooplankton concentrations that these larvae encounter, even during spawning seasons attuned with zooplankton production cycles, are usually far too low to allow survival of fish larvae, and the overwhelming majority of such larvae perish. Those that tend to survive usually happen to have hatched within plankton-rich water layers. These layers are usually a few centimeters thick and last for only a few days of calm, between wind-driven or other mixing events, such as storms or upwelling pulses that enrich surface waters with nutrients from deeper waters. This implies that large biomasses of fish can build up only when and where the local oceanographic conditions take the form of triads defined by (1) nutrient enrichment, such as generated by wind-driven mixing,

(2) high plankton concentration, such as generated by various mechanisms including fronts, and (3) retention of larvae, required to prevent these weak swimmers from drifting away from suitable habitat. In pelagic fishes that build high biomass, for example, the anchovies and sardines in coastal upwelling systems off northwestern and southwestern Africa, Peru, and California, these triads occur only when the coastal winds range from 4 to 6 m s⁻¹. Weaker winds do not generate enough enrichment, and stronger winds disperse the larvae offshore.

Fish have developed several strategies to deal with the uncertain recruitment that results from the triad requirements. One is being small, short-lived, and capable of quickly building up large biomass under favorable environmental conditions. The other is being large, long-lived, and capable of weathering long series of recruitment failures through repeated spawning by old, large, and highly fecund adults. An example of the former strategy is provided by the Peruvian anchovy *Engraulis ringens*, whereas the northern cod, *Gadus morhua*, provides an example of the latter. Yet another strategy is to reduce the dependence on environmental conditions by various forms of parental care, such as nesting and guarding (e.g., in catfishes, family Clariidae), mouth-brooding (e.g., in cardinal fishes, family Apogonidae), and live-bearing (e.g., in ocean perches, genus *Sebastes*).

Another important feature of fish populations is that, contrary to earlier assumptions of homogeneity, most appear to consist of well-differentiated individuals, each aiming to

Figure 2 Schematic representation of how changes in water level can multiply, by creating isolated subpopulations, the number of species occurring in a given area. Such a mechanism, driven by repeated climatic changes, is thought to explain the large number of fish species in Southeast Asian marine waters and in the Great Lakes of Africa.

reproduce at the very place where it was hatched. Or, in other words, most migratory fish tend to home. This behavior, well documented only in Pacific and Atlantic salmon (*Oncorhynchus* and *Salmo*, respectively), implies that individual fish, when reproducing, do not seek optimal sites, but rather spawn as close as possible to the site at which they hatched, and to which they are imprinted. This reproductive strategy has proven successful in evolutionary time scales. However, it is not helpful in cases where, for example, climate change or pollution have impacted traditional spawning grounds, or where a stock recovering from overfishing has to rediscover spawning sites that were abandoned during the depleted phase.

Respiratory Constraints to Growth and Related Processes

Basic Geometrical Constraints

Fish growth, as in other animals, requires both food and oxygen, the latter being required to synthesize the substance (adenosine triphosphate (ATP)) that serves as fuel to all organisms. For oxygen to be metabolically available, it must

be inside the body of the fish, that is, it must have passed through its gills. Thus, since oxygen cannot be stored inside the fish body (contrary to food, which can be stored as gut contents and as fat), the metabolic and growth rate of fish are largely proportional to the surface area of their gills. So fish that quickly reach large sizes have gills with large surface areas (as in swordfish, billfish, and tunas), and conversely in slow-growing fishes (like groupers). Moreover, gill area per unit of body mass declines with size, because the two-dimensional gill area cannot keep up with the three-dimensional increase in body mass. Hence larger fish dispose of relatively less oxygen to supply their metabolism, the reason why they ultimately stop growing. Furthermore, environmental factors that tend to increase metabolic rate – especially elevated temperature, and other forms of stress – have the effect of reducing the maximum size that the fish of a given population can reach (Figures 3(a) and 3(b)). This is why tropical fish tend to be smaller than their respective cold-water relatives.

Adaptation to Respiratory Constraints

Fish have evolved various strategies and tactics to overcome respiratory constraints. One strategy, illustrated in Figure 1(b),

Figure 3 Schematic representation of the relationships linking, in fish, respiratory area (and hence metabolic rate) and maximum body size. (a) As body size increases, gill area per body weight decreases, down to a level when it suffices only for maintenance metabolism. This defines the maximum size that can be reached. (b) Any environmental factor increasing oxygen demand for maintenance (such as elevated temperature) reduces the maximum size that fish can reach.

is to evolve large gills, a route taken by numerous open-water (pelagic) species, culminating not only in tunas but also in plankton feeders such as the basking shark. Another strategy is the evolution of life cycles in which the juveniles migrate to deeper, cooler waters as they grow and then, on maturing, produce eggs that quickly float up to the warmer surface layers, out of reach of the often cannibalistic adults. Such typical cycles are completed by an onshore drift of the larvae to coastal areas, and productive shallow nurseries for the early, voracious juveniles, which again migrate into deeper waters as they grow.

A tactic to accommodate metabolic stress, which is particularly useful in areas with strong seasonal temperature oscillations, is for the feeding adults to store fat during the warmer part of the season (late summer to early fall). Fat requires far less oxygen for maintenance than protein of muscle and other tissues. The accumulated fat is partly burned during the time of the year when food is scarce, and partly converted into other tissues, notably gonads, whose contents are shed in spring. As a result, body mass is reduced and the relative gill area increased when temperatures again start to rise. These cycles, which use fat as protection against respiratory stress, are the reason why temperate fish tend to contain more muscle fat and visceral fat than tropical species, where temperatures, although high, do not fluctuate much in the course of a year.

Another tactic that delays respiratory stress is associated with ontogenetic shifts in diet composition. Here, the young fish feed on a diffused, small prey (e.g., invertebrate zooplankton), whereas the adults, due to their sheer size, can capture energy-rich prey such as other fish, which are acquired at a lesser cost by the predator.

Relationships Between Growth, Mortality, and Maturity

The constrained growth of fishes with age is well described by the von Bertalanffy growth function. This function has an inflexion point where the increase in body weight per unit time is maximum. This is also the area where the expected body weight, that is, the product of body weight and the

probability of reaching that weight, has a maximum. A species which, for a single life-time spawning event, transforms a certain fraction of its body weight into gonads, maximizes its expected reproductive output and thus its fitness if it matures, spawns, and dies at the size and age of maximum growth rate. A species with multiple spawning events, all of which are likely to have the same average success rate, maximizes its fitness by maturing in such a way that the maximum growth rate falls roughly into the middle of the mean duration of the reproductive phase. However, a species where successful reproduction depends on rare and unpredictable environmental conditions will maximize its fitness by a trade-off between reproductive output and number of spawning events, that is, by maturing early. These different strategies are shown schematically in Figure 4. To maximize fitness, one-time spawners (A) will aim to mature at the peak of the blue curve, which represents the expected reproductive output. Bearers, nesters, and guarders (B), whose parental care ensures a certain success at every spawning event, increase their fitness by maturing such that their average reproductive phase (dotted line) maximizes the area under the blue curve. Highly fecund nonguarders (C), for which most spawning events will be unsuccessful, maximize their fitness by maturing early and thus increasing the number of spawning events. This maturation framework is confirmed by the data on length at first maturity shown in Figure 5. One-time spawners, bearers, and guarders mature close to and slightly before 0.67 asymptotic length, which is the size range where the growth rate in weight and the expected reproductive output have their maximum. In contrast, nonguarders mature at a significantly smaller size.

These considerations are highly relevant for the biodiversity of fish stocks, because exploitation typically commences before maturation and high fishing mortality reduces the average duration of the reproductive phase to only one spawning event. From Figure 4 it should be clear that this dramatically reduces the expected reproductive output of individuals and stocks, exerting unnatural selection for early maturation and provoking recruitment failures. Decrease in size and age at maturation and increase in recruitment failures are regularly observed in heavily exploited stocks.

Figure 4 Schematic representation of reproductive strategies in relation to probability of survival (red curve) and increase in body weight (green curve). The blue curve indicates the expected reproductive output. Strategy A represents single-spawners, such as salmon or eels. Strategy B represents multiple-spawners with parental investment, such as live-bearers, nesters, or guarders. Strategy C represents highly fecund nonguarders such as cods, sardines, or tunas. The dotted horizontal lines indicate the necessary duration of the reproductive phase.

Figure 5 Length at first maturity relative to asymptotic length for species that spawn only once in their life time (one spawners, five studies), bearers or guarders (49 studies), and nonguarders (178 studies). The horizontal lines within the boxes represent the median and the notched area the 95% confidence limits. The boxes contain 50% of the data and the extended lines indicate the spread of the data. The difference between bearers and guarders and nonguarders is significant.

Distribution of Exploited Fish Stocks

Overall Distribution Ranges

Although mostly confined to water, fish occur in a wider range of habitats than any other vertebrate or invertebrate group. Thus, fish range from the upper reaches of streams in high mountain ranges (e.g., river loaches, Balitoridae) to the

mouths of temperate and tropical rivers (e.g., gray mullets, Mugilidae). In the marine realm, fish range from the intertidal to the ocean's abyss, either as predators in their desert-like expanses (e.g., skipjack tuna, *Katsuwonus pelamis*) or as components of the rich, newly discovered deep-sea vent ecosystems (e.g., some live-bearing brotulas, Bythitidae). Environmental adaptations include the ability to deal with an enormous range of pressures (from about one to hundreds of atmospheres), temperatures (from -1.8°C in polar waters to about 40°C in hot springs, tolerated by some tilapias), and salinities (from close to distilled water preferred by the discus fish, *Symphysodon discus*, of Amazonia to about 10‰, e.g., in West African hypersaline coastal lagoons inhabited by the blackchin tilapia, *Sarotherodon melanotheron*), to list only three environmental factors. No single fish species or family, however, spans more than small fractions of these ranges. Rather, these various adaptations are exhibited by a bewildering variety of forms, ranging from minute gobies that are fully grown at close to 1 cm (e.g., *Mystichthys luzonensis*) to the 15 m reached by whale sharks (*R. typus*). These two species, incidentally, are exploited for food in the Philippines. The former, despite its turnover rate, is in danger of extinction in the small lake where it is endemic because of overfishing and pollution. The latter is now legally protected, but enforcement remains problematic.

Adaptations to Open-Ocean Habitats

Fish have different strategies to deal with the low production of the oceans. Tuna have adopted a high-energy strategy, where their tightly packed schools quickly move from one food patch to the other, essentially hopping from one oasis to the next and minimizing the time spent in the intervening desert-like expanses. Others, notably the lantern fishes (Mycetophidae), occur in scattered populations that, at dawn, migrate from 1000 m to the surface waters, and get back at dusk. These different strategies imply very different biomasses: tens of millions of metric tons for the major tuna species (prior to their recent depletion by various longline, purse seine, and other fisheries) against an estimated global biomass of one billion metric tons for the lantern fish and associated communities. The latter number is often viewed as a promising figure, from which various estimates of potential yields have been derived. Most of these estimates, however, do not consider the extremely dilute nature of this biomass (usually less than 1 g per metric ton of water).

Shelf Communities

Definition of Neritic Stocks

Most fish stocks are neritic, that is, occur above the continental shelves, the productive areas of shallow waters (down to 200 m) around the continents, from which about 90% of the world marine fisheries catches are extracted. Shelves may have rocky or soft (sandy or muddy) substrates, and usually support two weakly connected fish communities, one species-rich and consisting of bottom or demersal fishes, the other consisting of fewer species of open-water or pelagic fishes. The fish of demersal communities are those exhibiting the specialized fins

and mouths mentioned earlier, enabling utilization of distinctive food sources, particularly on reefs in both temperate and tropical regions.

On coral reefs, this fine partitioning of resources culminates in hundreds of fish species sharing a single reef, with dozens of specialists for each of its food resource types, from the filamentous algae consumed, for example, by damselfishes (Pomacentridae), the encrusting algae consumed by parrot fishes (Scaridae), the coral themselves, consumed by butterfly fishes (Chaetodontidae), to the small invertebrates consumed by, for example, wrasses (Labridae). A vast array of predators such as groupers (Serranidae) and sharks (Carcharhinidae) regulate the number of these smaller fishes. Hard-bottom shelves and, in tropical areas, the coral reefs that occur down to 30 m are also exploited wherever they occur. The fishing gear used over hard bottoms are mainly traps and handlines (the latter both sport and commercial), which are rather selective gears that would have relatively minor impacts were it not for their excessive numbers.

Demersal Fish Stocks

The demersal fish living in, on, or just above shelf soft bottoms consist of specialized flatfishes and rays and numerous generalized teleosts feeding on bottom invertebrates (the zoobenthos) and smaller fishes. The complex communities thus formed can reach very high biomass, at shallow depth in the tropics (20–50 m) and deeper in colder waters. In the warm waters of the tropics, bacteria induce a quick remineralization of the dead organic matter (detritus) falling out of the lighted part of the water column. This allows very little detritus to become available for consumption by the zoobenthos. In cold water, however, the short but intensive burst of algal production occurring in the spring is consumed only partly by the zooplankton of the upper water layers. Most of the remainder is consumed as detritus after falling down to the sea bottom as marine snow. Thus, cold-water soft-bottom communities can occur in very deep waters, down to the shelf slopes (200–300 m) and well beyond. Indeed, the latest trend in fisheries development is the exploitation of deep-sea stocks of cod-like fish (order Gadiformes), orange roughy (*Hoplostethus atlanticus*), and other fish, down to depths of 1000 m or more, through ventures that even in principle could never be managed so as to achieve sustainability.

Wherever they occur, soft-bottom shelves are nowadays invariably subjected to bottom trawling, a very unselective fishing method that is environmentally damaging. This involves dragging a heavy, chain-studded net over the sea bottom and catching, that is, removing all that it encounters. Not surprisingly, this procedure has often been compared to harvesting crops with a bulldozer. Trawler catches thus consist of targeted species (usually shrimps in the tropics and subtropics) plus a vast number of nontarget species, often the juveniles of demersals with large adult sizes, and literally parts of the habitat of bottom-fishes, notably sessile invertebrates and chunks of reefs lifted from the sea bottom. Nontarget species and debris are then discarded, and it is therefore trawlers that contribute most to the global discarding problem. Presently, about 10 million metric tons of various fish species are reported to be discarded, down from about 30 million metric tons two decades ago. This is still a very high

discard rate when compared to the 80 million metric tons that appear in global landing statistics.

The contribution of trawlers to habitat destruction, including conversion of richly structured bottom habitats into featureless expanses of mud, is well recognized, and can only be compared in terms of scale with global deforestation and the ensuing trend toward desertification.

Pelagic Fish Stocks

The pelagic communities over most shelf areas previously consisted of both major and minor stocks and stocklets of herrings, sardines (Clupeidae), anchovies (Engraulidae), and their relatives, and of their predators, notably mackerels and tunas (Scombridae) and various jacks (Carangidae). In many parts of the world, pelagic fisheries have eliminated the minor stocks and stocklets, and now depend wholly on annual recruitment to the remaining major stocks. The overfishing of old, highly fecund adults in these remaining stocks explains much of their volatility. Indeed, the present emphasis of much fisheries research on variability is thus devoted largely to a secondary phenomenon created by the activity itself. It is true, however, that pelagic stocks, feeding lower in the food web, often closely track environmental changes, such as the decline of the Peruvian anchovy *E. ringens* during El Niño events, and their subsequent rebuilding, mainly from recruits produced off northern Chile.

Pelagic fish tend to form tightly structured, dense schools, which protects them from predators and facilitates detection and herding of scattered food patches. The fisheries rely on this behavior when deploying purse seines, which can surround and catch such schools in one go, often with associated predators such as dolphins. Large pelagics such as billfish (Xiphiidae and Istiophoridae) are caught by arrays of longlines, set by the thousands along shelf edges, which also capture, besides the target species, large amounts of by-catch (notably sharks). These sharks were previously left on the spot, but are now finned before the carcasses are discarded. Longlines are indeed as unselective as the now banned giant driftnets that, in the 1980s, erected “walls of death” that were hundreds of kilometers long across the migratory routes of fish in the North Pacific and the Atlantic.

Overall Status of Neritic Stocks

When combined, the demersal and pelagic fisheries of shelves and adjacent waters represent major threats to fish biodiversity. Particularly endangered are groupers and other slow-growing bottomfish, and pelagics such as bluefin tuna and various species of sharks and billfish.

Besides the fisheries, one factor contributing to this endangerment is the traditional separation of research devoted to fisheries management (stock assessments) from that devoted to conservation and to ecosystem research. Both lines of research are separated institutionally, in terms of their methods and publication outlets, and in terms of what they perceive as their mandates. Overcoming this separation is crucial if fish biodiversity is to be maintained in the face of the onslaught by fisheries. Key needs are the development of tools and concepts for integrating information on fish biodiversity and ecosystem function with the knowledge gained through a century of applied, single-species fisheries research. Before

considering these, however, evidence for fisheries impacts on ecosystems will be presented.

Ecosystem Impacts of Fisheries

Historical Trends

The earliest fishing gear so far identified by archeologists are bone harpoons that were recovered, along with other evidence of systematic fishing, from a site 90,000 years old, in the present-day Democratic Republic of Congo (formerly Zaire). Tellingly, the main species that was targeted appears to have been a now extinct, very large freshwater catfish.

This pattern of fisheries exterminating the stocks on which they originally relied, then moving on to other species, is now understood to be common. This contradicts earlier perceptions of the ocean's quasi-inexhaustible resources, as expressed among others by Victorian grandees such as the geologist Charles Lyell and the zoologist Thomas Huxley. They were misled by the then prevailing abundance of various stocks of coastal fish (notably herring, *Clupea harengus*), and by what may be called "Lamarck's Fallacy:" the notion that "animals living in the waters, especially in sea-water ... are protected from the destruction of their species by Man. Their multiplication is so rapid and their means of evading pursuit or traps are so great that there is no likelihood of his being able to destroy the entire species in any of these animals."

The industrialization of the fisheries, first in Northern Europe and then in North America at the end of the nineteenth century, quickly showed these predictions to be wrong. Most coastal stocks of herring and other small pelagics were extirpated, and faded even from memory, there by coastal stocks of demersal fishes soon followed, after the introduction of bottom trawling.

The practical response to this was the introduction of bigger boats with bigger engines, fishing farther offshore. Another response was the creation of research bodies (such as the International Council for the Exploration of the Sea, founded in 1902) to assess the reason why the resources were declining. Further, several countries (notably Norway and the US) initiated costly programs where juvenile cod and other fish were raised in hatcheries and then thrown into the sea, in the vain hope that they would replenish the stocks rather than be eaten by happy predators (which they were, unhappily).

Emergence of the Sustainability Concept

The First World War put an end to most stocking programs. It also established that a strong reduction in fishing effort, as caused by the drafting of fishers and vessels into the war effort, and the spiking of major fishing grounds by underwater mines (thus creating the first marine protected areas), would lead to a recovery of depleted fish stocks. Yet the Second World War, and another demonstration of stocks rebuilding themselves when subjected to less fishing, was required for the notion of sustainable fishing to establish itself. This notion implies that some appropriate level of fishing effort (number of vessels or gear, mesh size) exists such that catches (or yield) can be maintained at high levels – hence the concept of maximum

sustainable yield (MSY). This led to the emergence of fish population dynamics and stock assessments, wherein mathematical models of single-species fish stocks and of their response to targeted fishing became the mainstay of fisheries research. Beverton, Holt, and Gulland in England, Ricker in Canada, and Schaefer in the US proposed most of these still-used models during an extremely creative period lasting from the early 1950s to the mid-1970s.

Yet in spite of these advances, the fisheries never became sustainable. One obvious reason was that, given a resource to which access was essentially open, the fisheries could never limit their collective effort at the level supposed to generate MSY. Rather, effort levels increased well beyond that, permitting some fleet owners to increase their stakes even as the aggregate rent from the fisheries declined. Subsidization of expanding offshore and distant water fleets has aggravated these economic issues, enabling commercial profits to be gained even from strongly overexploited stocks. These developments are so widespread that they have rendered obvious the impacts which fisheries have on ecosystems.

Biodiversity Trends in Global Catch Data

Since 1950, the Food and Agriculture Organization of the United Nations (FAO) has collected seafood catch data reported to them by the governments of the World. These data have been criticized as being incomplete, biased toward industrial fisheries, overaggregated both spatially and taxonomically, and unreliable as exemplified by some countries' continued reporting of high catches even after a typhoon had destroyed their fishing fleet. Yet, this is the only available global data set on fisheries, and it forms the basis for global fisheries policy. Attempts to predict global trends from a few hundred stocks for which complete assessments are available are flawed because of their spatial and survivorship biases, that is, the fact that such assessments are only available from developed countries for stocks that have withstood exploitation for decades and thus are more resilient to fisheries than the many stocks that have been quickly depleted, not meriting a full assessment.

The nominal catches of seafood organisms have reached about 80 million tons in 1988 and fluctuated around that level since then (Figure 6). This has been interpreted as a phase of stability, as if global fisheries had settled at a level that could be sustained indefinitely. A closer examination of the dynamics in the composition of these catches leads, however, to a very different interpretation, revealing severe impacts on the global fish stock biodiversity.

The number of exploited stocks has increased continuously and has more than tripled since 1950, meaning that from the beginning the increase in global catches did stem not only from increased exploitation of existing stocks, but also from exploitation of new stocks. It also means that the impact of fishing on the biodiversity of fish stocks has tripled in half a century.

During the same period, the number of depleted stocks has increased from close to zero to about one-third of all stocks in 2009. For the phase of perceived stability in total catches after 1988, this means that there is an underlying process where the

Figure 6 Underlying trends in global catch statistics. The bold curve shows the reported landings of seafood organisms. The number of exploited stocks, defined here as species by statistical marine area, is indicated by the upper thin curve. The number of depleted stocks, defined here as those producing less than 10% of their maximum contribution in the time series, is indicated by the lower thin line.

loss in catch from stock depletion is made up by new catches from new stocks. But the number of new stocks suitable for exploitation is limited, and if current trends continue we can expect to see an accelerated increase in depleted stocks and an accelerating decrease in global catches. The only remaining option for halting this trend is the rebuilding of depleted stocks, a process that has started in New Zealand, Australia, and the USA, but which has yet to reach a level where it makes a difference in global statistics.

Managing Fish Biodiversity Information

Biodiversity As a Conceptual Challenge

There is a widespread perception that the main obstacle to the conservation of fish stocks and of fish biodiversity is lack of data, a notion strengthened by public statements of biologists worried about the lack of funding for relevant research. However, simple lack of data cannot be the problem, not after the 250 years since Linnaeus created the taxonomic standards required for biodiversity research, after 100 years of applied fisheries research, and after at least 50 years of advances in ecosystem research. Rather, the problem here is the fragmentation of the database collected so far. Indeed, many studies conducted in recent years on the status of various stocks fail to consider previous knowledge on their relative abundance and distribution, and thus contribute to shifting baselines, wherein only the most recent and usually low estimates are used as reference for conservation or rebuilding efforts.

One reason for this reluctance of biologists to consolidate existing data into comprehensive, global databases may be due in part to the perception that biological data are too difficult to standardize, or are useless once standardized. Addressing

these issues will be a key task of biodiversity research, and the authors now present a few ideas related to this.

There is consensus that the objects of biodiversity research are genes, populations, species, and ecosystems. However, there is little consensus as to what distinguishes biodiversity from the existing disciplines of fisheries biology, ecology, biogeography, population genetics, or taxonomy. As a result, the array of data being claimed to be essential for biodiversity studies reads like a composite list of the data traditionally used in the older disciplines, with few attempts at integration or prioritization. Such integration and prioritization are possible, however, by giving emphasis, in biodiversity studies, to data that are: (1) relevant to current research issues (e.g., richness, rarity, distinctiveness, representativeness, threat, function, and utility of species); (2) part of the data traditionally collected in taxonomy, biogeography, population genetics, and ecology; (3) widely available, in sufficient quantity; (4) pertinent to past, present, and most likely future trends; (5) easy to collect; (6) easy to standardize; (7) easy to verify; and (8) suggestive of new lines of research.

Bioquads As Primary Biodiversity Data Sets

A minimum core of biodiversity information that fulfills these eight criteria is provided by bioquads (from quads, short for quadriads), consisting of (1) the scientific name of a taxon, usually a biological species or other evolutionarily significant unit; (2) the locality where a specimen of this taxon has been encountered; (3) the date (time) of the encounter; and (4) the authority or source reporting (1)–(3). A standard for scientific names (1) has been developed by the Catalogue of Life initiative (www.catalogueoflife.org), which provides an authoritative index of scientific names for more than 1.4 million species of the 1.8 million species that are thought to have been

formally described by taxonomists during the past 250 years. Standards for (2)–(4) have been set by the Global Biodiversity Information Facility (GBIF) and applied so far to more than 250 million bioquads, which are freely accessible from the GBIF portal at www.gbif.org. The number of bioquads is expected to increase rapidly as observations of lay persons are integrated into the system. The challenge now is to interpret these large amounts of data and to derive insights on marine biodiversity and the diversity of fish stocks. This task has been taken on by the AquaMaps initiative (www.aquamaps.org), which has published the first comprehensive global map of marine biodiversity (Figure 7). Although the map is based on only 11,500 of the estimated 250,000 species living in the oceans, it already shows the expected trends in global species richness, such as exponential decline in species numbers from the equator to the poles, higher diversity on the continental shelves, and the center of marine biodiversity in the Malaysian-Indonesian-Philippine triangle.

AquaMaps can also be used to depict changes in catches on fish stocks, which in many cases are driven by changes in abundance. For example, Figure 8 shows catches of Atlantic cod (*G. morhua*) in 1968 and in 2007. Available stock assessment data confirm that the visible strong decline in catches is a result of the strong decline in biomass, which itself is a result of previous overfishing.

Species Databases As Tools for Management of Biodiversity Information

Knowing the correct scientific name and the native range is a minimum requirement for a species to be included in one of the two biological databases available for marine organisms, FishBase (www.fishbase.org) for fishes and Seabase (www.sealifebase.org) for all other organisms. Both

databases extract and standardize key information from the scientific literature, such as diet composition, growth, reproduction, morphology, and physiology. They also record human use and the resilience of species. FishBase has been utilized extensively for understanding and management of fish biodiversity, with more than 1000 citations in the primary literature, and about half a million visits per month to the FishBase portal. Recent changes in legislation, for example, in the USA, require fisheries managers to provide reference points and assessments for all fished stocks, including many cases where no stock-specific data are available. To fill these gaps, FishBase is exploring Bayesian methods to derive priors from related stocks and species. It also provides empirical equations for preliminary estimates on, for example, resilience or size at first maturity. Following a general trend to preserve scientific data, FishBase is considering to store primary life history data, such as weight-at-age or fecundity-at-length, in addition to the published models fitted to such data. This will enable the reuse of such data with other models and for different questions.

Preserving Fish Biodiversity

Traditional Approaches to Stock Management

None of the foregoing considerations will however, help, if fisheries are allowed to continue undermining their resource base, which they will if fisheries management continues to rely on the panoply of approaches so far deployed. These traditional approaches include, among other things: (1) mesh size restriction; (2) restriction on the amount or species of fish that may be legally landed; (3) effort limitation, for example, through caps on the vessel tonnage that may be deployed; and (4) seasonal closures.

Figure 7 Marine species richness based on individual range maps for 11,500 species of fishes, marine mammals, and invertebrates. Species richness is depicted on a log scale from low (= yellow) to high (= dark red).

Figure 8 Catches of Atlantic cod distributed according to suitability of habitat. The upper map refers to 1968 whereas the lower map refers to 2007. Light yellow indicates catches of 1–400 t whereas dark-red areas yielded 1600–2100 t per year and half-degree cell.

Besides being extremely hard to enforce, these approaches – which are invariably conceived in the context of single-species assessments – fail to address the ecosystem effects mentioned earlier (*see* Ecosystem Impacts of Fisheries). Thus, mesh sizes above a certain limit, meant to protect the young of a given species, do not prevent associated species from being caught. Indeed, when combined with restrictions on total allowable catch (TAC), and on the landing of bycatch (as is often the case), mesh size restrictions become the very reason for discarding the young of both the targeted species and the nontarget species. Limits on nominal fishing effort are subverted by technological developments, such as improved gears and navigation instruments (e.g., GPS), which increase the catching power of fishing vessels. Thus, government-run vessel retirement schemes often end up subsidizing the modernization of fishing fleets. Finally, seasonal closure of various areas usually has negligible ecological impacts, because the fishing effort expended during the open season is sufficient for the sea bottom to be scraped up numerous times by trawlers, and for the stocks of long-lived fishes to be severely impacted.

Marine Protected Areas

There is an emerging consensus among fisheries scientists and conservationists that an important fisheries management tool

that will allow the recovery of damaged stock and ecosystems is the establishment of Marine Protected Areas (MPAs), including permanent No-Take zones as their core. Such core zones are easy to enforce – at least relative to the task of enforcing mesh sizes or TACs. Further, technology-driven increases in fishing effort can be ignored, and there is assurance that the long-lived organisms of seafloors and their associated fish communities can gradually return to a semblance of their original configurations. However, considerable research will have to be devoted to identifying the optimal size and location of MPAs, particularly for migratory stocks.

Traditional fisheries management, aimed at limiting effective fishing effort, will still have to continue around MPAs, lest they become marine larders or fish-attracting rather than fish-producing zones from where resources are drained by fisheries operating at their very periphery.

Finally, the social context of fisheries will have to change: fisheries do not harvest crops they have sown. Rather, they exploit the natural productivity of wildlife; thus there are inherent limits to global fish catches, and future fisheries will not meet the demand of an ever-increasing human population if these limits are ignored. Indeed, the massive ecosystem changes already described indicate that these limits have been reached in most parts of the world, and that sustainable fisheries must be embedded in some form of ecosystem management.

Glossary

Adipose fin A small, fleshy fin without supporting spines or rays, set far back on the dorsal surface of many catfishes, characins, salmon, and other groups.

Anadromy A form of diadromy where a fish is born in fresh water, matures in the ocean, and returns to fresh water to spawn (lampreys, sturgeons, salmon). Contrast with catadromy.

Ancestral The taxon from which descendant species are derived, often synonymized as primitive or generalized. Ancestral traits or conditions are those which appear in an ancestor.

Catadromy A form of diadromy where a fish is born in the ocean, matures in fresh water, and returns to the ocean

to spawn (freshwater eels, some mullets). Contrast with anadromy.

Depauperate Of low diversity, lacking in species; opposite of speciose.

Derived Later-appearing taxa within a lineage, often synonymized as advanced or specialized. Derived traits are those which appear in a descendant species and are changed from the ancestral condition.

Endemic Restricted or native to a geographically defined area.

Extant Living; opposite of extinct.

Speciose Of high diversity, having many species in a group or area.

Taxon (plural = taxa) A group of evolutionarily related species.

Taxonomic Diversity

Overview

Approximately 32,000 known fish species inhabit the earth's oceans, estuaries, rivers, lakes, and streams. This incredible diversity exceeds that of all other vertebrate groups combined (**Box 1**). It forms a wealth of biological wonder for ichthyologists (fish scientists), but such large numbers can be overwhelming to someone unfamiliar with the many taxonomic groups and their names. However, the different taxonomic groups are logically arranged according to well-studied evolutionary relationships, with those more closely related to groups that evolved earlier in geologic time (so-called ancestral or primitive taxa) placed earlier in lists and those groups that evolved relatively recently (derived or advanced taxa) placed later in lists (Nelson, 2006).

The most primitive of the living fishes are the jawless fishes. These arguably include 22 species of marine lancelets, and less

arguably about 115 species of marine hagfishes and freshwater or anadromous (migratory between freshwater and marine) lampreys. Cartilaginous sharks, skates, rays, and chimaeras include approximately 10 orders, 43 families, and 1300 species of almost entirely marine, relatively large-bodied predators. Skates and rays are more diverse than sharks, constituting about 55% of all cartilaginous fishes. Chimaeras are cartilaginous fishes distantly related to sharks that consist of 3 families and 46 species.

Bony fishes make up the vast majority of living fish species, exceeding all other groups in species, habitat, reproductive, and feeding diversity (**Figure 1**). Bony fishes vary in length from the 8-mm pygmy gobies and Indonesian minnows to the 8-m-plus long Oarfish, 900-kg marlins, and 1000-kg-plus Ocean Sunfish. There are perhaps 45 orders and 435 families among the approximately 31,000 species of bony fishes, ranging from the relatively primitive lungfishes, coelacanths, sturgeons, bichirs, gars, and Bowfin to the more advanced

Box 1 What is a fish and what are fishes?

Generally defined, a fish is a cold-blooded, aquatic-living chordate with fin-like appendages, a body covered with scales, and that breathes using gills. Exceptions to and variations in all traits are common (Paxton and Eschmeyer, 1998). Some sharks, tunas, and billfishes are warm-blooded. Fins can be unsegmented and spiny or segmented and soft rayed (and soft rays can be hardened). Tail types include: (1) the heterocercal tail of sharks and sturgeons, in which the notochord or vertebral axis extends considerably into the upper tail lobe; (2) the abbreviated heterocercal tail of gars and Bowfin, in which the vertebral axis extends only slightly into the upper lobe; (3) the leptocercal or diphyocercal tail of lungfishes, the coelacanths, and rattails, in which vertebrae or tail rays extend through the middle of the tail, forming a pointed tail; and (4) the homocercal tail of most advanced bony fishes, in which the vertebral column ends at the tail base (the urostyle) and fin rays form a symmetrical, two-lobed tail. Scales also vary in terms of the number of layers of bony material that constitute them and the extent of spiny projections that cover their surface; more primitive fishes generally have heavier scales, and more advanced fishes have lighter scales, often with more projections. Scale types include the placoid scales of sharks, the ganoid scales of gars and bichirs (and sturgeons), the cycloid scales of lower teleosts, and the ctenoid scales of higher teleosts. But unlike familiar groups of vertebrates such as birds and mammals that can trace their roots back to some common ancestor, "fishes" include a tremendous diversity of groups with different ancestries. Hence our definition can include lancelets, hagfishes, lampreys, sharks, lungfishes, and bony fishes, each evolving from a different ancestral group.

To ichthyologists, "fish" refers to one or more individuals of a single species, whereas "fishes" refers to more than one species, regardless of how many individuals are involved. Hence, this article is about fishes (Moyle and Cech, 2004; Barton, 2006; Helfman *et al.*, 2009).

Figure 1 Anatomical features of a hypothetical bony fish. Reproduced from Squire Jr. JL and Smith SE (1977) *Angler's Guide to the United States Pacific coasts*. Washington, DC: National Marine Fisheries Service.

teleostean (higher bony fish) groups that include bony-tongues, eels and tarpons, herring-like fishes and the so-called true teleostean groups of minnows, salmon, various deepsea taxa, and cods. The spiny-rayed teleosts are the most evolutionarily advanced of the fishes and include mullets, silversides, scorpionfishes, perch-like fishes, tunas, flatfishes, and triggerfishes (Helfman and Collette, 2011).

Phylum Chordata Subphylum Cephalochordata; order Amphioxiformes (lancelets, two families, 30 species, marine, tropical and temperate) Subphylum Vertebrata Superclass Agnatha Class Myxini; order Myxiniformes (living hagfishes; one family, 70 species, temperate marine) Class Cephalaspidomorphi; order Petromyzontiformes (living lampreys; three families, 38 species, temperate fresh water and anadromous).

Cephalochordates

Lancelets may not really be fishes because they lack scales, fins, and gills. However, their evolutionary and anatomical affinities are similar to what most workers believe characterized the ancestors of fishes, and lancelets are studied primarily by ichthyologists. Lancelets possess a dorsal nerve tube, in common with all vertebrates. They also have a notochord, which is a cartilaginous rod that runs the length of the body and is shared with all embryonic vertebrates as well as with the adults of many primitive living fishes. Lancelets are small (to 3 cm), slender organisms that as adults occupy sandy, usually shallow bottoms in all major tropical and temperate oceans. A commercial fishery for lancelets involving bottom dredging exists in southern China. The fishery is in apparent decline.

Agnathans

The first fishes lacked jaws. Modern jawless fishes – hagfishes and lampreys – look approximately similar, with slippery, eel-like bodies and jawless heads. The fossil record, however,

indicates that they have been separated evolutionarily for hundreds of millions of years. Hence, most similarities are due to convergent or parallel evolution.

Hagfishes

Hagfishes, known also as slime eels or slime hags, produce copious mucus from many pairs of slime glands (Figure 2). A couple of disturbed 2-ft-long hagfish can fill a 5-gallon bucket with slime. However, a hagfish covered in its own slime will suffocate. To rid itself of slime, a hagfish ties a knot in its tail and passes the knot forward until the slime is pushed off. Hagfishes are nocturnal predators on small invertebrates but are better known for their scavenging behavior, which involves burrowing into a dead or dying fish and consuming the prey from the inside.

Hagfishes occur almost worldwide in temperate and cold-temperate oceans, usually in water deeper than 30 m. Hagfishes can reach high densities upwards of 0.5 m^{-2} on soft-bottom marine areas, which is the most abundant habitat type in the world. Hence, hagfishes could be ecologically important as predators and scavengers. They are also common in the diets of seals and sea lions. Hagfishes are commercially important because their hides are the popular “eel-skin” of wallets, purses, and briefcases. Overfishing has depleted hagfish stocks in Korea and Japan, and new fisheries are being exploited, and probably overexploited, in the eastern Pacific and western Atlantic. This unfortunate chain of events has characterized marine fisheries worldwide (Helfman, 2007). Drastic reductions in hagfish populations brought on by overfishing could potentially disrupt a widespread ecosystem; not enough is known about hagfish ecology to predict these impacts.

Lampreys

Lampreys also have a notochord rather than vertebrae. Lampreys go through a long-lived larval phase; the free-living, blind, toothless larva lives in silty streambeds where it filters

Figure 2 Hagfishes, also called slime eels, produce prodigious amounts of mucus when disturbed. Photo by Meyer JL.

microscopic organisms from the water for up to 7 years before transforming into an adult. In brook lampreys, larvae transform into nonfeeding adults, live for 6 months, spawn, and die. Other species transform into feeding adults and live for 1–3 years as parasites on other fishes. They rasp holes in their host's skin and live off its body fluids (**Figure 3**). Accidental introduction of the parasitic Marine Lamprey into the Great Lakes of North America has contributed to the decline of Lake Trout, whitefishes, and Blue Pike.

Lampreys are cool-water species (30° north and south latitude or higher). Most lampreys live in fresh water, but some parasitic species are anadromous. Brook lampreys typically live in headwater streams, an ecosystem type frequently disrupted by human activities. Hence, several US brook lampreys are imperiled. North America's smallest lamprey, the Miller Lake Lamprey, was poisoned almost into extinction because it parasitized introduced trout in its only habitat – Miller Lake, Oregon.

Cartilaginous Fishes

Elasmobranchs (sharks, skates, and rays) include perhaps 1300 species that live in all the world's oceans; a few live in fresh water (Carrier *et al.*, 2004, 2010). Elasmobranchs are characterized by a cartilaginous skeleton hardened by calcium deposits and usually five (sometimes six or seven) gill slits. They lack lungs or gas bladders but instead have large, oil-filled livers which may aid in buoyancy. Their teeth and pedestal-like placoid scales develop from the same embryonic structures. Teeth are continually lost and replaced, and a shark may produce as many as 30,000 teeth during its lifetime. All elasmobranchs have internal fertilization, and many bear live young that are nourished by the mother *via* a complex

Figure 3 Mouth region of a lamprey. Lampreys attach to the sides of larger fish and scrape a hole with their tongue, feeding on body fluids.

umbilicus and placental structure analogous to that found in mammals. Slow growth, late maturation, and low reproductive output make many elasmobranchs exceptionally vulnerable to human exploitation.

Class Chondrichthyes: cartilaginous fishes Subclass Elasmobranchii: shark-like fishes Infraclass Euselachii: sharks and rays Division Neoselachii Subdivision Selachii sharks Superorder Galeomorpha Order Heterodontiformes: 1 family, 8 species, bullhead and horn sharks Order Orectolobiformes: 7 families, 32 species, including wobbegongs, nurse, and Whale sharks Order Carcharhiniformes: 8 families, 224 species, including catsharks, requiem, and hammerhead sharks Order Lamniformes: 7 families, 15 species, including ragged tooth, Tiger, Megamouth, thresher, Basking, and mackerel sharks Superorder Squalomorpha Order Hexanchiformes: 2 families, 5 species, Frill and cow sharks Order Echinorhiniformes: 1 family, 2 species Order Squaliformes: 6 families, 97 species, including sleeper and dogfish sharks Order Squatiniformes: 1 family, 15 species, angel sharks Order Pristiophoriformes: 1 family, 5 species, saw-sharks Subdivision Batoidea skates and rays Order Torpediniformes: 2 families, 59 species, torpedo electric rays and numbfishes Order Rajiformes: 4 families, 295 species, guitarfishes, skates Order Myliobatiformes: 10 families, 183 species, stingrays, butterfly rays, eagle rays, and manta rays.

Sharks

Approximately 465 shark-like species are alive today. Sharks are generally large (>1 m), predatory fishes. The diverse requiem or ground sharks (carcharhiniforms) include the Tiger,

Gray Reef, Bull, Blue, lemon, and hammerhead sharks. Lamniform mackerel sharks are primarily offshore, pelagic inhabitants, although White Sharks spend considerable time close to beaches and small islands, especially where seals and sea lions abound. The squaliform dogfishes, the second largest shark order, are most successful and abundant in the North Atlantic, North Pacific, and deepsea regions.

Sharks range in size from the 15-g, 16- to 20-cm Dwarf Dogshark to the 12,000-kg-plus, 12-m-long Whale Shark, the largest fish in the world. White Sharks as large as 6 m and 3324 kg are known; larger individuals are suspected. Other large sharks include Basking Sharks (9.8 m), Great Hammerheads (5.5 m), Greenland Sharks (6.4 m), Tiger Sharks (5.9 m), and Megamouth (5.4 m).

Sharks inhabit all oceans except the Antarctic. Depth records for sharks are held by the Portuguese Shark at 3690 m and an unidentified dogfish at 4050 m. A few carcharhinid sharks enter fresh water; Bull Sharks have been captured 4200 km up the Amazon River and 1200 km up the Mississippi River. Large pelagic sharks may cross entire ocean basins; Blue Sharks have been tracked across the North Atlantic Ocean and back, a distance of 16,000 km, and a White Shark moved from South Africa to Western Australia and back to South Africa over a 9 month period, a distance of 22,000 km.

Most sharks are predatory on large prey, but three of the largest sharks – the Basking, Megamouth, and Whale sharks – feed on zooplankton. A small, 40-cm-long, midwater species, the Cookie-Cutter Shark, is an ectoparasite on the sides of tunas, dolphins, whales, an occasional Megamouth Shark, and even rubber sonar domes of nuclear submarines. Some sharks use structures other than jaw teeth to capture prey. Thresher sharks use the long upper lobe of their tails to stun schooling prey. Saw-sharks (and rajiform sawfishes) have elongate, blade-like snouts studded with lateral teeth which they slash laterally to disable prey. Hammerheads use their broadened hammer-shaped head to pin stingrays against the bottom before biting chunks out of the rays' wings.

Sharks are sensitive to chemicals, able to detect 1 part fish extract per 10 billion parts seawater. Sharks have good vision, although they tend to be slightly myopic (farsighted). Sharks are also highly sensitive to sounds, including infrasonic sound below 10 Hz, and can localize the direction from which underwater sounds originate, something humans cannot do. Sharks can also locate prey by detecting the weak electric fields their prey emit. This electro-sensitivity may also allow them to navigate using the earth's geomagnetic fields. Many sharks have relatively large brains, with brain to body weight ratios comparable to those of some birds and mammals.

Sharks grow slowly and live long: Spiny Dogfish live 70–100 years and Lemon Sharks 50–60 years. Sharks also reproduce slowly. Lemon Sharks may not mature until they are 24 years old, and Spiny Dogfish may not mature until they are 35 years old. Sharks produce relatively few, large young with a long gestation period. Clutch size varies from 1 or 2 live young (Ragged Tooth, threshers, and makos) to 300 in the Whale Shark. Gestation periods average 9–12 months but may be 2 years in Spiny Dogfish and 3.5 years in Basking Sharks. Bullhead and nurse sharks lay eggs, but most sharks bear live young. The requiem sharks have the most advanced developmental pattern, in which an umbilical cord connects mother and embryo, transporting nutrients and oxygen to the embryo and carrying metabolic wastes to the mother.

Because many sharks mature late, reproduce at long intervals, and have low reproductive output, shark populations are easily and frequently overfished (**Figure 4**). Thresher sharks, School Sharks, Spiny Dogfish, Porbeagles, Basking Sharks, Bull Sharks, and Soupfin Sharks are all examples of shark stocks that have been overexploited. White Sharks are protected in Australia, South Africa, and the US; capture and sale of White Sharks, Whale Sharks, and Basking Sharks is restricted under the Convention on International Trade in Endangered Species (CITES).

Figure 4 Ragged Tooth Sharks, also called grey nurse and sand tiger sharks, have suffered declines because of fishing and as by-catch in nets. Ragged Tooth sharks are protected in several countries. “Raggies” are relatively docile, adapt well to captivity, and are often featured in public aquaria.

Skates and Rays

The batoid skates and rays are 535 species of mostly benthic (bottom-living), mostly marine forms. In skates and rays, the pectoral fins are fused to the sides of the head and the five gill slits are under the head. Skates are most diverse in deep water and at high latitudes, whereas stingrays are most diverse in tropical, inshore waters. Some batoids live much or all of their lives in fresh water. Largetooth Sawfish frequently swim up rivers in Central and South America. Two stingray families contain entirely freshwater species – the river stingrays of South America and several species in the large stingray family *Dasyatidae*. The latter inhabit African, Southeast Asian, and New Guinea rivers.

Skates and rays feed mostly on benthic invertebrates, except for the huge (up to 6-m wide) manta rays, which capture small crustaceans and fishes in the water column. Torpedo rays stun prey with powerful electrical discharges (50 V and 50 A = 1 kW output). Batoids reproduce by either laying eggs (skates) or bearing live young (rays). Embryonic skates develop inside “mermaid purse” egg cases for as much as 15 weeks (Figure 5).

Figure 5 A mermaid purse (egg case) of a Big Skate, *Raja binoculata*, from the North Pacific. Each case holds a single embryo, which can be seen because part of the egg shell has been removed. Some skates are overfished because they are born at a size that is already too large to escape through the mesh of drag nets.

Skates in some locales are actually increasing in number because of overexploitation of competing bony fishes, such as cod in the North Atlantic. However, the giant Barndoor Skate of the northwest Atlantic and its relative, the ironically named Common Skate of the northeast Atlantic, are caught incidental to bottom trawling for bony fishes; they have been seriously depleted and may face extinction. Largetooth Sawfish in Nicaraguan lakes have been drastically overfished.

Chimaeras

Class Chondrichthyes Subclass Holocephali Order Chimaeriformes: 3 families, 46 species, chimaeras.

Chimaeras, also known as rat- or rabbitfishes, share a cartilaginous skeleton and other features with elasmobranchs. They differ by having (1) the upper jaw permanently attached to the braincase, (2) continually growing tooth plates in the jaws instead of replaceable teeth, (3) a single gill flap instead of five or more gill slits, and (4) no scales. Chimaeras swim by flapping their pectoral fins (something sharks never do) and by undulating their bodies (Figure 6). All chimaeras are egg-layers, the egg being protected by a horny shell. Adult chimaeras range in size from 60 to 200 cm. Chimaeras are cool-water, marine fishes that live at shallow to moderate depths between 80 and 2600 m, where they usually swim just above the bottom. Chimaeras eat predominantly hard-bodied benthic invertebrates, which they crush with their tooth plates. Surprisingly little is known about their general biology and natural history.

Bony Fishes

Modern bony fishes, often referred to as Osteichthyes (literally “bony fishes”), consist of seven major taxonomic orders. Many living members belong to groups that were much more diverse during Paleozoic and Mesozoic eras. Several of these primitive but modern fishes are classified as “bony” even though they have cartilaginous skeletons. Their skeletal condition is actually an advanced, specialized trait; their immediate ancestors were bony.

Figure 6 A Pacific Ratfish, *Hydrolagus coliei*, showing the beak-like mouth, flexible pectoral fin, and lack of scales that set chimaeras apart from sharks and rays. The large, reflective eye is characteristic of fishes that live in deep, dark waters.

Grade Teleostomi (more commonly Osteichthyes) Class Sarcopterygii Subclass Coelacanthimorpha Order Coelacanthiformes: 1 family and 2 species, the coelacanths Subclass Dipnoi Superorder Ceratodontimorpha Order Ceratodontiformes: 1 family and 1 species, the Australian lungfish Order Lepidosireniformes: 2 families, 5 species, South American and African lungfishes Subclass Tetrapoda (amphibians, reptiles, birds, mammals) Class Actinopterygii Subclass Cladistia Order Polypteriformes: 1 family, 16 species, bichirs and Reedfish Subclass Chondrostei Order Acipenseriformes: 2 families, 27 species, sturgeons and paddlefishes Subclass Neopterygii Order Lepisosteiformes: 1 family, 7 species, gars Order Amiiformes: 1 family and species, the Bowfin.

The Coelacanths

Coelacanths were thought to have gone extinct at the end of the Cretaceous, 65 million years ago, until a live one was trawled up in 1938 off South Africa. Today, one small population of 200–600 coelacanths, *Latimeria chalumnae*, lives at 100- to 500-m depths off two small volcanic islands in the Comore Archipelago, between Madagascar and Mozambique. Other populations of the same species have been discovered along Africa's eastern coast from South Africa to Tanzania. In 1998, another species, *L. manadoensis*, was discovered at similar depths in northern Indonesia. The living coelacanths have fleshy pectoral, pelvic, anal, and second dorsal fins (= the lobed fins that define the class Sarcopterygii); a symmetrical, three-lobed tail with a central extension; hollow neural spines (hence "coelacanth" or "hollow spines"); a unique uncontracted notochord; a joint in the dorsal braincase that aids jaw opening; relatively large, thick, bony scales; and live young.

Coelacanths are large (to 180 cm, 95 kg), old (probably 40–50 years), and produce relatively few, live young (five to 26 young per clutch). The gestation period is about 13 months. Replacement rate in a population is therefore slow. Coelacanths are captured primarily as by-catch in the hook-and-line fishery for Oilfish, and it is unlikely that the Comore population can sustain even the current by-catch rate of five to 10 animals per year. Counts from small submarines indicate the Comoran species is declining. The Comoran government has outlawed its capture, and trade in coelacanths is outlawed by the Convention on the International Trade in Endangered Species (CITES).

Lungfishes

Lungfishes today are represented by three families and six species, all located on the former Gondwanan continents of Australia, South America, and Africa. Lungfishes lack jaw teeth but have unusual tooth plates on the mouth roof and floor. The Australian species, *Neoceratodus forsteri*, is limited to four river systems of northeastern Australia. It is large (1 m), with large scales, flipper-like fins, a broad tail, and a single lung. It crushes benthic crustaceans, mollusks, and small fishes with its tooth plates. It can, but does not have to, breathe atmospheric oxygen. Its young lack external gills. *Neoceratodus* populations have declined dramatically and the fish is protected; species recovery efforts include transplantation into several Queensland reservoirs and rivers.

The one South American and four African lungfishes have eel-like bodies; slender, almost-filamentous paired fins; lack scales; have paired lungs; have larvae with external gills; and must breathe air to survive. The four African species occur across central and south Africa, often in swampy areas that frequently experience drought (Figure 7). When a swamp dries up, African lungfishes dig a burrow and can wait 4 years for rains to return. The South American species occurs in swampy regions of the Amazon and Parana river basins. Comparatively little is known about its biology.

Tetrapods

Recent paleontologic, anatomic, and genetic discoveries indicate that the 26,734 species of tetrapods (modern amphibians, reptiles, birds, and mammals) are in reality a subclass of the fleshy-finned sarcopterygians. An exciting, confirming fossil discovery, the "fishapod" *Tiktaalik roseae*, was unearthed in 2005 in Nunavut Territory of Arctic Canada. Tetrapods are therefore a sideline taxon of fishes that moved onto land and into the air, with some groups such as turtles, whales, and seals returning to an aquatic existence. We are all fish.

Bichirs and Reedfish

The polypteriform bichirs and Reedfish of west and central tropical Africa have been difficult to assign to any particular taxonomic group. Their gilled larvae, lobe-like fins, thick ganoid scales, and modified heterocercal tail suggest affinities with several living groups, particularly the chondrosteian sturgeons and paddlefishes. However, their unique dorsal, caudal, and paired fins and unusual chromosomes place them apart from all extant groups. Their placement near the base of the bony fish lineage is justified by egg structure, genetics (mitochondrial, nuclear, and other DNA and amino acid sequences), and head skeleton. Taxonomists now place them in their own subclass, the Cladistia.

Ten species of polypteriforms are called bichirs (*Polypterus*) and an 11th, elongate species is the Reedfish or Ropefish,

Figure 7 African lungfishes, *Protopterus*, estivate, burrowing into mud and remaining inactive for years while waiting for rains to return. Photo courtesy of Chapman L and Chapman C.

Erpetoichthyes. Bichirs reach 120 cm in length and Reedfish 90 cm. All are predatory and inhabit shallow, swampy regions, where they breathe atmospheric oxygen with their paired lungs. Bichirs, also called “flagfins,” have unique dorsal and pectoral fins. Each dorsal finlet consists of a vertical spine with attached horizontal rays, looking like a flagpole with streaming banners. In more usual ray-finned fishes, dorsal fin rays emerge vertically from the body of the fish. The polypteriform pectoral fin has an internal arrangement that involves a wishbone-shaped, flattened plate, again unlike that in any other fish. Bichirs are not particularly well studied; no evidence exists to suggest they are imperiled.

Sturgeons and Paddlefishes

The next-most primitive actinopterygian (ray-finned) fishes are the chondrosteian sturgeons and paddlefishes. All 25 species of sturgeons live in the Northern Hemisphere. All spawn in fresh water, although some species move seasonally between marine and fresh water. North American freshwater species include the Lake Sturgeon and three river sturgeons. Anadromous species include the Atlantic and White sturgeons, the latter being an occupant of west coast bays and rivers. White Sturgeons attain the largest size of any North American freshwater fish (3.8 m, 630 kg). The world’s largest freshwater fish is the Beluga Sturgeon of eastern Europe and Asia, *Huso huso*, at 8.6 m and 1300 kg (Figure 8).

Sturgeons have four barbels ahead of a ventrally located mouth, five rows of large bony shields on an otherwise scaleless body, and a heterocercal tail. They are exceptionally long-lived (118 years for Beluga and 70–80 years for White Sturgeon), mature slowly (as late as 30 years old), and spawn infrequently (every 3–5 years). They migrate up rivers to spawn in clean sand and gravel areas; hence, dam building and siltation of rivers impede their reproduction. A spawning female can be worth thousands of dollars for her caviar alone, and many sturgeon stocks have been reduced 99% from historical levels. The Shortnose Sturgeon of Atlantic coastal rivers is listed as endangered, and Lake Sturgeon have been extirpated from a large part of their native range. Three species endemic to the Aral Sea may be extinct due to extensive drying of that once huge body of water, and several species in the former Soviet Union are fished mercilessly.

Figure 8 Beluga Sturgeon, *Huso huso*, may be the world’s largest and most valuable freshwater fish. The eggs or caviar from a single, large female can be worth thousands of dollars.

Two species of paddlefishes occur in large rivers of North America and China. Paddlefishes also have a heterocercal tail, unconstricted notochord, largely cartilaginous skeleton, and scaleless body. The most distinctive feature of the paddlefishes is their paddle or spoonbill, which is flat and rounded in the North American Paddlefish and elongate and almost spear-like in the Chinese Paddlefish. Paddlefishes are water column swimmers that feed on zooplankton and fishes. The paddle of the North American species may help direct food into its mouth, but abundant electroreceptor cells on the paddle suggest an additional, unknown function. North American Paddlefish may live 30 years and grow to be 2.2 m in length and 83 kg in weight. Late maturation (at 10 years of age), infrequent spawning (every 2–5 years), lack of clean gravel spawning habitat, and overfishing have all contributed to population reductions and range contraction. The exceedingly rare and poorly studied Chinese Paddlefish is larger, reaching more than 3 m in length. This paddlefish may be the most endangered fish in China because of overfishing, habitat destruction, pollution, and dam construction that blocks spawning migrations in the Yangtze River basin where it lives. Recent construction of the Three Gorges Dam in China may have sealed the fate of the Chinese species.

Gars

The lepisosteiform gars are seven species of elongate, predaceous fishes that occur in eastern North America, Cuba, and Central America. They typically inhabit backwater areas of lakes and rivers, such as oxbows and bayous, and breathe atmospheric oxygen using a highly vascularized gas bladder. Gars have bony skeletons, but their vertebral centra are unique, being convex anteriorly and concave posteriorly. In most fishes, the vertebrae are concave on both surfaces. Gars have an abbreviate heterocercal tail (vertebral column extends into the top lobe of the tail) and hinged, diamond-shaped, interlocking ganoid (heavy and bony) scales. Gars are the only freshwater fish in North America with poisonous eggs. Alligator Gars can be 3 m long and weigh 140 kg (Figure 9). In recent years, Alligator Gars have come under intense commercial fishing, and concern for their well-being is increasing.

Figure 9 An Alligator Gar, *Atractosteus spatula*, one of the largest freshwater fishes in North America. Photo courtesy of Jean-Francois Healias, www.anglingthailand.com.

The Bowfin

The Bowfin, *Amia calva*, is the only living member of its genus, family, and order. The Bowfin has the abbreviate heterocercal tail and spiral valve intestine of the gars but also has teleost-like biconcave vertebrae as well as cycloid scales, a relatively light scale type also possessed by many teleosts. The Bowfin's head is exceptionally bony and the throat is covered by a distinctive large bone, the gular plate. Bowfin swim slowly forwards or backwards by passing undulations back and forth along their long dorsal fin. Bowfin occur throughout much of eastern North America in backwater, often swampy areas; they also have a highly vascularized gas bladder which functions as a lung. They are relatively large and robust (to 1 m and 9 kg) and predatory on anything that moves. Bowfin males guard the young vigorously until they are relatively large (10 cm).

Teleosts

The division Teleostei ("perfect bone") contains most living fishes. Teleosts are not only taxonomically diverse but also ecologically diverse, occupying every aquatic habitat type and niche imaginable. The 27,000 living teleostean species are placed in 4278 genera, 448 families, and 40 orders. This incredible diversity is generally organized into four taxonomic subdivisions that reflect patterns of evolution that date back to the Mesozoic. These four main subdivisions are the osteoglossomorphs (bonytongues), elopomorphs (eels and tarpon), otocephalans (herrings and minnow relatives), and the euteleosts, with the latter group containing the vast majority of modern bony fishes.

Class Actinopterygii

Subclass Neopterygii Division Teleostei Subdivision Osteoglossomorpha Order Hiodontiformes: 1 family, 2 species, mooneyes Order Osteoglossiformes: 6 families, 218 species, including bonytongues, African knifefishes, and elephantfishes.

Osteoglossomorphs derive their name "bonytongue" from the teeth on their tongue that forms part of their bite. These freshwater fishes occur on all major continents except Europe. The hiodontiforms comprise two species, the Mooneye and Goldeye, both of which occur in major river systems of northern North America. The osteoglossiforms are much more diverse. The Asian Arowana or Golden Dragonfish, *Scleropages formosus*, has been depleted in the wild due to overcollecting and is now protected under Appendix I of the Convention on International Trade in Endangered Species (Figure 10). The Arapaima of South America is one of the world's largest freshwater fishes, reaching a length of 2.5 m. The African mormyrid elephantfishes produce and detect weak electric fields, have large cerebellums, and have a brain size: body weight ratio comparable to that of humans.

Subdivision Elopomorpha

Order Elopiformes: 2 families, 8 species, ladyfishes and tarpons Order Albuliformes: 3 families, 30 species, including bonefishes and spiny eels Order Anguilliformes: 15 families, 738 species, including freshwater, moray, cutthroat, and conger eels Order Saccopharyngiformes: 4 families, 28 species, including swallower and gulper eels.

Figure 10 The Asian Arowana or Golden Dragonfish (*Scleropages formosus*, Osteoglossidae), an internationally protected species. Desirable color varieties have sold for as much as \$5000. Photo by Marcel Burkhard, Wikimedia Commons, <http://en.wikipedia.org/wiki/Image:Arowanacele4.jpg>

Elopomorphs all have ribbon-shaped leptocephalus ("pointed head") larvae. The Atlantic Tarpon is a highly prized gamefish that reaches a length of 2.5 m and a mass of 150 kg. Albuliform bonefishes are also popular gamefishes that occupy sandy flats in shallow tropical waters. The 15 families of anguilliform "true" or freshwater eels are distinguished from the approximately 45 other families of "eel-like" fishes that have independently evolved an elongate body. Anguillid eels are catadromous, spawning at sea but spending most of their lives in fresh water. Muraenid moray eels and their relatives are marine, tropical and warm-temperate, predatory species. Synbranchid cutthroat eels include an endoparasitic species, the Snubnose Parasitic Eel, which has been found in the heart of a mako shark. The saccopharyngiform deepsea gulper and swallower eels have giant mouths but lack many head bones, scales, and fins found in most other fishes.

Subdivision Otocephala

Superorder Clupeomorpha Order Clupeiformes: 5 families, 364 species, including anchovies and herrings.

Clupeomorphs are small, schooling, silvery, pelagic marine and occasionally freshwater feeders on zooplankton and phytoplankton. Herrings, round herrings, shads, alewives, sprats, sardines, pilchards, and menhadens are extremely important commercial species. Anchovies range in size from a 2-cm Brazilian species to a piscivorous, riverine, 37-cm New Guinea anchovy. The largest clupeids are the Indo-Pacific chirocentrid wolf herrings, which reach a length of 1 m and have fang-like jaw teeth. Anadromous shads, Alewife, and herrings occasionally establish landlocked populations in rivers, lakes, and reservoirs.

Superorder Ostariophysii Order Goniorhynchiformes: 4 families, 37 species, including milkfish Order Cypriniformes: 6 families, 3268 species, including minnows, barbs, algae eaters, suckers, and loaches Order Characiformes: 18 families, 1674 species, including freshwater hatchetfishes, tetras, and characins Order Siluriformes: 36 families, 2867 species, including North American freshwater, airbreathing, electric,

sea, upside-down, parasitic, callichthyid armored, and suckermouth armored catfishes Order Gymnotiformes: 5 families, 134 species, including glass, ghost, and naked-back knife-fishes and Electric Eel.

Rivers, lakes, and streams worldwide are dominated numerically and ecologically by members of the superorder Ostariophysi. Ostariophysans include minnows, carps, barbs, suckers, loaches, piranhas, tetras, catfishes, and electric eels. Two distinctive traits unite this otherwise disparate assemblage: (1) the Weberian apparatus, which is a series of modified anterior vertebrae that link the gas bladder to the inner ear and aid in hearing, and (2) production and reaction to chemical alarm substances that are released when a fish is injured and lead to a stereotyped escape response in school members.

The gonorhynchiform Milkfish, *Chanos chanos*, is an important food fish in the Indo-Pacific region and is often cultured in brackish fish ponds. The Cypriniformes make up the largest order in the superorder. The Cyprinidae is the largest family of freshwater fishes and contains 3268 species of minnows, shiners, carps, barbs, barbels, gudgeons, chubs, dace, pikeminnows, Tench, Rudd, bitterlings, bream, southeast Asian “sharks” (Redtail Black Shark and Bala Shark), Goldfish, Koi (domesticated common carp), danios, and rasboras. Cyprinids are most diverse in Southeast Asia, followed by Africa, North America (270 species), and Europe, but are missing from South America and Australia. The world’s smallest freshwater fish is an Indonesian cyprinid, *Paedocypris progenetica*, that matures at 7.8 mm. The largest minnow in North America is the endangered, piscivorous Colorado Pikeminnow, *Ptychocheilus lucius*.

Gyrinocheilid algae eaters scrape algae off rocks in swift, flowing waters. The catostomid suckers (i.e., buffaloes, Quill-back, carpsuckers, Blue Sucker, redhorses, jumpfrocks, and the extinct Harelip Sucker) include 72 species of North American fishes, with 1 species in eastern China and another in Siberia. Loaches (Cobitidae) are 177 species of predominantly Eurasian stream fishes, including popular aquarium fishes such as the kuhli, Clown, and skunk loaches, the weatherfishes, and the Golden Dojo. Weatherfishes (*Misgurnus*) become restless when barometric pressure decreases preceding a storm.

The characiforms are a speciose group of primarily tropical ostariophysans characterized (usually) by a rayless adipose fin and mouths armed with replacement dentition (e.g., piranhas) (Figure 11). Body size ranges from very small (13 mm) tetras to large (1.5-m-long) tigerfishes. Numerous aquarium fishes are included (headstanders, freshwater hatchetfishes, blind characins, pencilfishes, tetras, and silver dollars), as well as important food fishes (*Prochilodus*, *Colossoma*, and *Brycon*). Most characins (ca. 1300+ species) are South American, about 200 are African, a few live in Central America, and 1 species, the Mexican Tetra *Astyanax mexicanus*, extends naturally into southwestern Texas.

Catfishes (Siluriformes) are surprisingly diverse, with 36 families and more than 2900 species. Catfishes usually have barbels (whiskers) and sometimes toxic spiny fins, and they are almost entirely freshwater, nocturnal, and benthic (a notable exception being the marine Striped Catfish, *Plotosus lineatus*, which is active by day). Catfishes are most diverse in South America (e.g., loricariid suckermouth armored catfishes,

Figure 11 Piranhas (subfamily Serrasalminae) belong to the incredibly diverse order of characiform fishes that dominate South American fresh waters. Although certainly capable of dismembering prey, most reported attacks on humans involved drowning victims.

684 species; trichomycterid pencil catfishes, 201 species, and callichthyid armored catfishes, 177 species). Large species include the European Wels (5 m, 330 kg), the Asian Mekong Giant Catfish (3 m, 300 kg), and a 3-m-long whiskered pimelodid of South America. The largest catfishes in North America are the Flathead and Blue catfishes at about 1.5 m and 50–68 kg. Some small catfishes are notable, such as the parasitic catfishes (Trichomycteridae) of South America, which normally parasitize the gills of fishes but one species, the Candiru, is known to swim up the urethra of male bathers and lodge there, necessitating surgical removal.

The gymnotiform South American knifefishes are unusual ostariophysans that produce and detect weak electric impulses. They have elongate, compressed bodies; an extremely long anal fin; and electrogenic tissue usually derived from modified muscle cells. Their electrical output is constant at high frequencies, whereas the osteoglossomorph mormyrids produce a pulsed, low-frequency output. Both groups detect objects that disrupt their electric fields. The 2-m-long Electric Eel (*Electrophorus*), a gymnotid, produces a weak field for electrolocation and strong pulses for stunning prey or deterring predators.

Subdivision Euteleostei

Approximately 2/3 of the teleosts are placed in the Euteleostei or true teleosts, a vast assemblage of more advanced fishes. This subdivision contains 346 families, 2935 genera, and 17,419 species – all in nine superorders.

Superorder Protacanthopterygii Order Argentiniformes: 6 families, 202 species, including barreleyes, pencilsmelts, and slickheads Order Salmoniformes: 4 families, 154 species, including smelts, galaxiids, Salamander Fish, whitefishes, graylings, charrs, trouts, and salmon Order Esociformes: 2 families, 10 species, pikes and mudminnows.

Protacanthopterygians are a mixed agglomeration of marine, freshwater, and diadromous fishes. Argentiniforms are

mostly deepwater marine species. Osmeriforms are small, silvery, elongate, water column dwelling fishes.

Salmoniforms are important commercially, ecologically, and esthetically. Whitefishes and ciscoes are relatively large-scaled, zooplanktivorous salmonids of high-latitude North American and Eurasian lakes. Several North American species have been decimated due to introduced predators, competitors, and parasitic lampreys. Graylings are riverine fishes with a flowing dorsal fin. At least one species, the Michigan Grayling, is extinct. The subfamily Salmoninae contains seven Eurasian and North American genera. The Siberian Taimen, *Hucho taimen*, is the world's largest salmonid at 2 m and 70 kg. North American Salmoninae include the chars (Lake, Brook, and Bull trout, Arctic Char, and Dolly Varden). Arctic Char live farther north than any other freshwater fish. The remaining salmonines are the Atlantic basin salmon and trout (e.g., Atlantic Salmon and European Brown Trout), and the 11 species of Pacific basin trouts and salmons in the genus, two of which are endemic to Japan. Pacific trouts and salmons include Golden, Cutthroat, and Gila trouts and the spectacularly anadromous Coho, Chinook, Chum, Pink, and Sockeye salmons, some of which undergo oceanic migrations of thousands of kilometers before returning to their birth river to spawn and die (Figure 12). The Rainbow Trout is a sixth species of Pacific salmon and is called a Steelhead Salmon if it spends part of its life at sea. The actual number of genetically distinct races of Pacific salmons is unknown because many stocks are reproductively isolated in small river systems. Evidence suggests that as many as 1000 stocks exist, more than 100 of which have gone extinct and an additional 300+ of which are imperiled. Osmerids include commercially important species such as capelins, eulachons, Asian Ayu, and smelts. The order Salmoniformes also includes the Southern Hemisphere salamander fish and the galaxiids. Salamander fish inhabit seasonal ponds of southwestern Australia, burying in drying mud and reemerging with the next rains. Galaxiids

have suffered numerous extirpations and extinctions as a result of the stocking of nonnative trouts.

Esociform pikes, pickerels, and mudminnows are Northern Hemisphere predators, including the 1.4 m Muskellunge; the Northern Pike has the largest geographical distribution of any Northern Hemisphere fish, occurring across the northern portions of North America, Europe, and Asia. Mudminnows can survive winters in high-latitude lakes by breathing from air bubbles trapped under the ice.

Superorder Stenopterygii Order Stomiiformes: 5 families, 391 species, including bristlemouths, marine hatchetfishes, and barbeled dragonfishes.

Stenopterygians are deepsea fishes, often with long teeth and large mouths. Gonostomatid bristlemouths may be the most abundant and widely distributed vertebrates on Earth. Idiacanthine black dragonfishes have a larva with eyes at the ends of elongate stalks.

Superorder Ateleopodomorpha Order Ateleopodiformes: 1 family, 12 species, jellynosefishes.

The jellynosefishes are elongate deepwater marine fishes that swim just above the bottom. Their large, pointed head and pointed tail are traits they share with other deepsea fishes such as chimaeras, spiny eels, halosaurs, eucla cods, rattails, and grenadiers.

Superorder Cyclosquamata Order Aulopiformes: 15 families, 236 species, including telescopefishes, tripodfishes, lizardfishes, and lancetfishes.

Cyclosquamates are also deepsea forms, including the bizarre giganturid telescopefishes with large tubular eyes, a huge mouth, flexible teeth, and an expandable stomach. Deepsea tripodfishes have long pectoral, pelvic, and caudal rays that they use for resting on soft sediments of the deep ocean floor.

Figure 12 A spawned-out, dead Sockeye Salmon, *Onchorhynchus nerka*, in an Alaskan stream. Spawning runs of Sockeye and other Pacific salmon species play a pivotal role in the ecosystems of the Pacific Northwest. Bears, eagles, etc. feed on spawning fish, and dead fish provide nutrients for food webs, including promoting growth of the large trees that shade the streams essential for survival of young salmon.

Shallow representatives are the synodontid lizardfishes, which are common benthic predators on coral reefs worldwide. Alepisaurid lancetfishes are large (to 2 m) mesopelagic predators with a sail-like dorsal fin of unknown function.

Superorder Scopelomorpha Order Myctophiformes: 2 families, 246 species, including lanternfishes.

Scopelomorphs include the abundant, commercially important lanternfishes, which are identified based on species-specific photophore (light organ) patterns. Lanternfishes occur at middle depths from the Arctic to the Antarctic. They are important in the diets of many fishes as well as of marine mammals.

Superorder Lampriomorpha Order Lampridiformes: 7 families, 21 species, including opahs, tube-eye, ribbonfishes, and Oarfishes.

Lampriforms are generally open-water, oceanic fishes. Opahs are relatively large (1.8 m, 70 kg), oval-shaped, pelagic predators on squids and other fishes. The 30-cm-long tube-eye (*Stylephorus*) can increase the volume of its mouth 40-fold during feeding – a record among vertebrates. The elongate Oarfish, *Regalecus*, may attain 12-m length and is the longest living teleost. It has a bluish-silvery body, scarlet head crest, and deep red fins. It is thought to be responsible for many “sea serpent” sightings (Figure 13).

Superorder Polymixiomorpha Order Polymixiiformes: 1 family, 10 species, beardfishes.

Superorder Paracanthopterygii Order Percopsiformes: 3 families, 9 species, troutperches, pirate perch, and cavefishes Order Gadiformes: 9 families, 555 species, including rattails, hakes, and cods Ophidiiformes: 5 families, 385 species, including pearlfishes, cuskeels, and viviparous brotulas Order Batrachoidiformes: 1 family, 78 species, toadfishes Order Lophiiformes: 18 families, 313 species, including goosefishes, frogfishes, handfishes, batfishes, and deepsea anglerfishes.

Paracanthopterygians are primarily benthic, marine, nocturnally active fishes; many live in the deep sea or in caves.

Percopsiforms are small (<20 cm), freshwater fishes, most of which live in eastern North America. The anus of the swamp-dwelling aphrododerid Pirate Perch is located in the throat region of adults for functionally mysterious reasons. Amblyopsid cavefishes are often blind and scaleless forms highly adapted for cave life.

The gadiforms include the cods, haddocks, hakes, pollocks, and whittings, which are some of the world’s most important commercial fishes. True cods (Gadinae) have three dorsal fins and two anal fins. Many species have chin barbels. The Burbot, *Lota lota*, of high-latitude, Northern Hemisphere lakes is the only freshwater species in the group. The commercially important Atlantic Cod is the largest species (1.8 m, 90 kg), but fish more than 10 kg are rare due to drastic overfishing. One of the world’s largest food fisheries is for North Pacific Walleye Pollock.

Ophidiiforms often live in holes or even inside other animals. Carapid pearlfishes live inside the body cavities of starfishes, sea cucumbers, clams, and sea squirts; some feed on the internal organs of their hosts. Ophidiid and bythitid cuskeels and brotulas include blind cave species in freshwater systems of Caribbean and Galapagos Islands as well as coral reef species that hide deep within crevices. The neobythitine cusk eel, *Abyssobrotula galathea*, holds the depth record for a fish at 8370 m in the Puerto Rico Trench.

Batrachoidiforms include the midshipmen, which have hundreds of photophores, an unusual trait for a shallow dweller. Many batrachoidids produce sounds by vibrating their gas bladders. Venomous toadfishes have dorsal and opercular spines that can inject a powerful toxin. Three South American toadfishes are restricted to fresh water.

Lophiiforms are a diverse and often bizarre-looking order of marine fishes that include benthic, shallow-water forms as well as highly modified, open-water, deepsea forms. Many use a modified first dorsal spine as a lure for catching smaller fish (see Figure 20). The meter-long western North Atlantic Goosfish, *Lophius americanus*, has a huge mouth with long, recurved teeth that it uses to catch fishes and even diving seabirds. Antennariid frogfishes also rest on the bottom or walk over it with their pectoral and pelvic fins. The ogcocephalid batfishes walk on their pectorals, but they can also

Figure 13 The Oarfish, *Regalecus glesne*, is probably the longest bony fish in the world and is responsible for many reports of sea monsters. This individual died at a shoreline in Mexico. Photo courtesy of Michael Kanzler.

swim *via* jet propulsion by shooting water out their round, backward-facing opercular openings. The ceratioid anglerfishes include 11 families of strange appearing bathypelagic predators, many of which have very small males that fuse to and become parasitic on the larger females. The endemic Australian handfishes include a Tasmanian species, the Spotted Handfish, that was once common but is now critically endangered due possibly to egg predation by an introduced starfish.

Superorder Acanthopterygii

Most bony fishes belong to a single superorder, the Acanthopterygii, which contains about 14,800 species in 267 families. Two small and one large taxonomic groupings, called series, are recognized, with the vast majority in the third series, the Percomorpha.

Series Mugilomorpha Order Mugiliformes: 1 family, 72 species, mullets.

The mullets are a family of near-shore, marine and freshwater fishes of considerable economic importance. Many mullets feed on organic silt and minute plants, an unusual food type among fishes.

Series Atherinomorpha Order Atheriniformes: 6 families, 312 species, including rainbowfishes and silversides Order Belontiiformes: 5 families, 227 species, including needlefishes, flyingfishes, and halfbeaks Order Cyprinodontiformes: 9 families, 1013 species, including topminnows, killifishes, livebearers, and pupfishes.

Atherinomorphs are shallow-water, marine or freshwater fishes that live near the surface. Many atherinomorphs bear live young. Atheriniforms include the melanotaeniid rainbowfishes of Australia and New Guinea, in which males have brighter colors and longer fins than females, traits that make them popular aquarium species. Silversides are widespread, freshwater and marine schooling fishes and include the grunions of southern and Baja California that ride waves up beaches on dark nights to spawn in wet sand biweekly during the summer. Belontiiforms are predominantly silvery, marine fishes active at and sometimes above the surface of the water. The lower lobe of the tail in flyingfishes is relatively long and is used to scull rapidly during takeoff. Many cyprinodontiforms, although basically freshwater fishes, tolerate considerable salinity and hence occur in streams on isolated oceanic islands. The rivulines of South America and Africa live only 1 year, laying eggs that survive in the dried bottoms of pools and that hatch with the next season's rains. *Kryptolebias marmoratus* of south Florida and the West Indies is the only truly hermaphroditic fish, fertilizing its own eggs. The livebearers include the mollies, platys, guppies, and swordtails of the aquarium trade. Some species are all female. Many cyprinodontid pupfishes are tolerant of extreme water conditions and consequently can live in saltmarsh and desert conditions. However, they cannot tolerate total desiccation, which has endangered many desert species that have to compete with humans for water. The Devil's Hole Pupfish has the smallest known range of any fish species – one shallow shelf in a single spring in Death Valley, California. Other pupfish relatives

inhabit Lake Titicaca, which at an elevation of 4570 m in the Andes Mountains is the highest natural lake with fishes.

Series Percomorpha Order Stephanoberyciformes: 9 families, 75 species, including whalefishes.

Order Beryciformes: 7 families, 144 species, including flashlight fishes, roughies, and squirrelfishes.

Order Zeiformes: 6 families, 32 species, including dories and boarfishes.

Order Gasterosteiformes: 11 families, 278 species, including sticklebacks, pipefishes, seahorses, seadragons, trumpetfishes, and shrimpfishes.

Order Synbranchiformes: 3 families, 99 species, including swamp and tiretrack eels.

Order Scorpaeniformes: 25 families, 1477 species, including scorpionfishes, rockfishes, sea robins, sablefishes, greenlings, sculpins, Baikal oilfishes, and lumpfishes.

Order Perciformes (10,000 species).

Suborder Percoidea: 79 families, 2860 species, including snooks, temperate basses, sea basses, centrarchid sunfishes, black basses, darters, perches, cardinalfishes, bluefishes, remoras, dolphinfishes, jacks, pompanos, snappers, grunts, croakers, drums, goatfishes, archerfishes, butterflyfishes, and angelfishes.

Suborder Elasmobranchii: 1 family, 6 species, pygmy sunfishes.

Suborder Labroidei: 6 families, 2200+ species, including cichlids, surfperches, damselfishes, wrasses, and parrotfishes.

Suborder Zoarcoidei: 9 families, 340 species, including eelpouts, gunnels, and wolffishes.

Suborder Notothenoidei: 8 families, 125 species, including icefishes and Antarctic dragonfishes.

Suborder Trachinoidei: 13 families, 212 species, including sand lances, weeverfishes, and stargazers.

Suborder Blennioidei: 6 families, 818 species, including clinids and blennies.

Suborder Icosteioidei: 1 family and species, Ragfish.

Suborder Gobiesocoidae: 1 family, 140 species, clingfishes.

Suborder Callionymoidae: 2 families, 182 species, dragonets.

Suborder Gobioidae: 8 families, 2211 species, including sleepers and gobies.

Suborder Kurtoidei: 1 family, 2 species, nurseryfishes.

Suborder Acanthuroidei: 6 families, 129 species, including spadefishes, scats, rabbitfishes, Moorish Idol, and surgeonfishes.

Suborder Scombroidei: 1 family and species, the Scombroidei.

Suborder Scombroidei: 4 families, 114 species, including barracudas, mackerels, tunas, Swordfish, and billfishes.

Suborder Stromateoidae: 6 families, 70 species, including driftfishes and butterfishes.

Suborder Anabantoidae: 3 families, 120 species, gouramies.

Suborder Channoidae: 1 family, 29 species, snakeheads.

Suborder Caproidae: 1 family, 11 species, boarfishes.

Order Pleuronectiformes: 14 families, 678 species, including flounders and soles.

Order Tetraodontiformes: 9 families, 357 species, including triggerfishes, boxfishes, trunkfishes, cowfishes, puffers, porcupine fishes, burrfishes, and ocean sunfishes.

The percomorphs constitute by far the largest taxonomic group of fishes, far too many to deal with in any detail. What follows is a very brief overview of some of the more interesting orders, suborders, and families.

Beryciforms are shallow- to moderate-depth, often red, almost always nocturnal fishes, including the reef-dwelling squirrelfishes. Also included is the commercially important Orange Roughy, *Hoplostethus atlanticus*, of high-latitude, southern ocean regions. Orange Roughies are being overexploited because they are slow growing and long-lived, taking more than 20 years to mature and reaching ages of more than 100 years. Zeiforms include commercial species such as the European John Dory, *Zeus faber*.

Gasterosteiforms are small marine, estuarine, and freshwater fishes with dermal armor plating. Sticklebacks are well-studied fishes that frequently form distinct, isolated populations characterized by unusual spines, plates, and behavior. The suborder Syngnathoidae includes the bizarre pegasid seamoths and syngnathid pipefishes, seadragons, and seahorses. Syngnathid pipefishes and seahorses are the only vertebrates in which the female impregnates the male by laying eggs in his brood pouch, which he then fertilizes and raises until hatching. Seahorses are heavily overfished for medicinal uses and the aquarium trade.

Synbranchiforms are primarily freshwater, eel-like, often airbreathing fishes. Swamp eels have recently been introduced into the southeastern United States and are of major concern as potential invading predators in river systems.

Scorpaeniforms are predominantly marine fishes, with spiny heads and sometimes venomous fin spines (i.e., stonefishes, scorpionfishes, and lionfishes) (Figure 14). The sebastine rockfishes are a diverse, commercially important, long-lived, and overfished group of the temperate North Pacific, some of which live to be over 200 years old. Hexagrammid greenlings are littoral zone (inshore and shallow water) and kelp-associated fishes endemic to the North Pacific,

including the highly edible Lingcod, *Ophiodon elongatus*. The suborder Cottoidei includes many freshwater species, including the cottid sculpins of North American streams and the highly divergent (pelagic and livebearing) comephorid oilfishes of Lake Baikal in northern Asia. The Cabezon of the Pacific coast of North America is unusual in having toxic eggs, whereas the lumpfish of the North Atlantic produces valuable caviar and has consequently been overfished.

The Perciformes are the largest order of percomorphs, with 160 families and over 10,000 species, including most marine and freshwater fishes of littoral zones. Perciforms reach their greatest diversity on coral reefs, but they are also highly diverse in rivers, streams, and lakes. Coral reef perciforms include six of the eight largest fish families (gobies, wrasses, sea basses, blennies, damselfishes, and cardinalfishes). Two other large families, cichlids and croakers, are characteristic of tropical lakes and near-shore temperate marine habitats, respectively.

The largest perciform suborder is the Percoidei. Many percoids are bass-like fishes. Centropomids are large predatory fishes and include the snooks of tropical America, the Barramundi of Australia, and the Nile Perch of Africa. Nile Perch are an introduced predator in Lake Victoria, in which they are thought to have extinguished perhaps hundreds of endemic cichlids. Moronid temperate basses include the Striped and White bass of North America. The sea bass family Serranidae is one of the largest families (475 species) that range in size from small (<5 cm) anthiines and hamlets to giant groupers (3 m long, 400 kg) (Figure 15). Sea basses also include commercially important hinds, coney, Gag, and Scamp. Many serranids are hermaphroditic, usually maturing first as female and then later becoming male, although some hamlets are both male and female simultaneously.

The Centrarchidae contains the sunfishes, crappies, rock basses, and black basses of North American fresh waters. Largemouth Bass have been introduced extensively as a sport fish. At least 201 species make up the family Percidae, 187 of

Figure 14 Lionfishes, *Pterois*, belong to the order of scorpionfishes, many of which have toxic spines. Lionfishes are native to Indo-Pacific regions. They have few natural predators, which has contributed to their success as an invasive introduced predatory species on tropical western Atlantic reefs. Photo by Jens Petersen, from Wikimedia Commons, File:Pterois_volitans_Manado-e_edit.jpg.

Figure 15 Large groupers, such as this Giant Grouper, *Epinephelus lanceolatus* from the Indo-Pacific, grow as large as 2.7 m long and can weigh over 400 kg.

which occur in North America. Percids include the Yellow and Eurasian perch, Walleye and Sauger (=pikeperches), and about 184 species of small, stream-dwelling, spectacularly colored, and often imperiled darters (Jelks *et al.*, 2008).

Apogonid cardinalfishes are diverse (273 species), small (<10 cm), nocturnal coral reef fishes. Cardinalfishes mouth-brood their eggs, an unusual trait among reef species. The voracious, schooling pomatomid Bluefish, *Pomatomus saltatrix*, occurs in most temperate and semitropical oceans except the eastern Pacific. In echeneid remoras or sharksuckers, the modified first dorsal fin forms a suction disk that is used to cling to various hosts. The coryphaenid dolphinfishes or mahi mahis are two species of open-water, pelagic predators that often associate with floating structure. They are also one of the few marine pelagic fishes that is successfully aquacultured. Carangid scads, jacks, pompanos, and amberjacks are a large family (140 species) of tropical near-shore predators.

Lutjanid snappers include 105 species of generally carnivorous marine fishes. Snappers are usually near bottom dwellers (i.e., Gray Snapper, Red Snapper, and Mangrove Snapper), but some are water column zooplanktivores (Vermilion Snapper).

Haemulid grunts are moderate-sized coral reef fishes and are most diverse in the New World tropics. They are seen most often in their daytime resting schools around coral heads; at night they disperse to feed in surrounding reef and grass areas. Sciaenid croakers (270 species) have chin barbels and a muscularized gas bladder used for sound production. Sciaenids are a widespread family that is particularly diverse in the southeastern US, but representatives occur widely in tropical marine and freshwater habitats. Species include Red Drum (spot tail bass), Black Drum, croakers, weakfish, sea trouts, kingfishes, White Sea Bass, corbinas, and the endangered Mexican Totoaba, one of the few unquestionably imperiled marine fishes. The range of the Freshwater Drum, *Aplodinotus grunniens*, includes much of eastern North America into Central America. Another bottom-oriented family is the tropical reef-dwelling mullid goatfishes, which have movable, muscularized chin barbels. Toxotid archerfishes are Indo-Pacific, brackish-water fishes well-known for their ability to shoot droplets of water that knock insects out of overhanging vegetation.

Two closely related, colorful reef families are the chaetodontid butterflyfishes (122 species) and the pomacentrid angelfishes (74 species). Both families are most diverse in the Indo-Pacific region. Butterflyfishes feed on coral polyps, small invertebrates, tube worms, or zooplankton, whereas angelfishes eat attached invertebrates such as sponges, tunicates, and anthozoans.

Elassomatoid pygmy sunfishes are a suborder of miniature (20- to 45-mm), colorful freshwater swamp dwellers of the southeastern United States.

Several very speciose families belong to the suborder Labroidei. Tropical marine families include the pomacentrid damselfishes (315 species), which are small, colorful, usually herbivorous, territorial reef dwellers. Some are zooplanktivores (*Chromis* and anemonefishes). Several occupy temperate regions (e.g., the Garibaldi of California, see Figure 19). The largest labroid family is the mostly tropical, reef-dwelling wrasses and parrotfishes (Labridae, 500 species).

Wrasses range in size from the 5-cm-long cleaner wrasses, Slippery Dicks, and Blueheads to the 2.3-m-long Maori or Humphead Wrasse of the Indo-Pacific, which is hunted unmercifully for the live fish restaurant trade. Cool temperate species include the California Sheephead and Senorita, western Atlantic Tautog and Cunner, and the eastern Atlantic Cuckoo Wrasse. Many wrasses change sex from female to a more colorful male. The parrotfishes (83 species) are almost exclusively coral reef dwellers, best known for their fused parrot-like teeth that are used for biting off algal and coral pieces, which are then crushed in the massive pharyngeal (throat) jaws. The embiotocid surfperches are 23 species of deep-bodied, temperate (mostly eastern Pacific) fishes associated with kelp beds and rocky reefs. They are livebearers, feeding on zooplankton or small invertebrates. The largest labroid family is the freshwater cichlids, with more than 2000 species (Barlow, 2000). Cichlids are chiefly tropical, South American and African fishes, with a few species that occur further north (the Rio Grande Cichlid is found in south Texas). Central and South American species include freshwater angelfishes, discus, Oscars, Convict Cichlids, and Peacock Bass. Most cichlids occur in Africa, where they are particularly speciose in the African Great Lakes and are threatened by introduced predators such as Nile Perch (Figure 16). African tilapias and other cichlids have been deliberately or accidentally introduced into Florida, California, and Hawaii as a byproduct of aquaculture activities.

Fishes of the suborder Zoarcoidei are all eel-like, bottom-living, marine, cool- to cold-water species. They range in size from the small, intertidal pricklybacks and gunnels to the live-bearing eelpouts, some of which live 3000 m below the surface. The large (to 2.5 m long) anarhichadid wolffishes and wolf eels of shallow North Pacific and Atlantic waters are anatomically and ecologically similar to moray eels.

Icefishes (suborder Notothenioidei) are mostly Antarctic, mostly benthic fishes that live under the ice and have antifreeze compounds in their blood. The crocodile icefishes lack red blood cells, hemoglobin, and myoglobin, and hence have colorless blood and flesh.

Trachinoids are marine, generally benthic fishes that tend to bury themselves in sand. Ammodytid sand lances are small, elongate, and abundant zooplankton feeders that spend their nights buried. Trachinid weeverfishes occur in the eastern Atlantic and Mediterranean and have venomous opercular and dorsal spines. Uranoscopid stargazers emit strong pulses of electricity (up to 50 V) from highly modified eye muscles.

Blenniods are small marine fishes that usually associate with structure. Chaenopsid pikeblennies and tubeblennies often live inside corals and worm tubes. Combtooth blennies are diverse (360 species) small fishes in tropical and subtropical waters; they scrape algae with their comb-like teeth.

The suborder Icosteioidei consists of the peculiar North Pacific Ragfish, *Icosteus aenigmaticus*, which has a largely uncalcified, cartilaginous skeleton and is a preferred food of sperm whales. The small, marine and freshwater gobiesocid clingfishes are shallow-water and even amphibious fishes often found in high-energy wave zones. Their pelvic fins are modified into a sucking disc.

Gobioids are usually small, benthic, often abundant fishes. The eleotrid sleepers are small to medium (to 60 cm)

Figure 16 Cichlid fishes in the Great Lakes of Africa are highly diverse ecologically and anatomically, with more than 1000 species in the major lakes. These cichlids at the Georgia Aquarium in Atlanta are representative of what one might see diving in Lake Malawi, Africa.

estuarine and stream fishes in tropical and subtropical areas, often on islands. The gobiid gobies are incredibly diverse (about 2200 species). Many gobies have a suction disk formed by fused pelvic fins. The family includes the amphibious mudskippers. Gobies range in size from tiny pygmy gobies (i.e., 8- to 10-mm adults) to a comparative giant, the western Atlantic Violet Goby, which is a purplish eel-like fish 50 cm long. Round Gobies have recently been introduced into North American Great Lakes from southern Europe and are spreading rapidly; other introduced goby species are now extremely common in San Francisco Bay.

The suborder Acanthuroidei includes the ephippid spade-fishes of Atlantic reefs and beaches as well as the Indo-Pacific scatophagid scats, which get their name from feeding on the feces of other animals. Rabbitfishes are Indo-Pacific reef, grassbed, and estuarine herbivores that are convergent in many ways with some butterflyfishes, a description that also applies to the Moorish Idol (Zanclidae). The 72 species of usually herbivorous acanthurid surgeonfishes, unicornfishes, and tangs have a knife blade on the caudal peduncle.

The suborder Scombroidei contains some of the largest and most spectacular marine fishes. Twenty species of barracudas inhabit tropical and subtropical oceans almost worldwide. The gempylid snake mackerels (24 species) are pelagic and deep-water predators, including the cosmopolitan Oilfish, *Ruvettus pretiosus*, a large (1.8 m, 45 kg) predator of moderate depths. An active fishery for oilfish in the Comoro Islands captures endangered Coelacanth as by-catch. The scombrid mackerels and tunas are quintessential open-sea predators, with streamlined bodies and a physiology geared to a high-speed lifestyle. They range from relatively small, 50-cm mackerels to giant Bluefin Tuna (4 m, 500 kg). Most are schooling fishes of tremendous commercial importance; a single, 340 kg Bluefin

Tuna sold for \$400,000 in Tokyo in 2011. The temperate and warm-temperate xiphiid Swordfish and the more tropical istiophorid sailfishes, spearfishes, and marlins have an elongate upper jaw bone that forms the bill. It is used as a spear, a cutlass, or a billy. Swordfish grow to 530 kg, whereas Blue and Black marlin grow to 900 kg. Swordfish have been heavily overfished, particularly in the Atlantic, although revised management plans have reduced fishing pressure and the species has shown signs of a comeback.

Labyrinth fishes (Suborder Anabantoidei) have an auxiliary breathing structure in the gill chamber for aerial respiration. Anabantid climbing gouramies are African and Asian freshwater fishes that can move across wet ground and reportedly up wet tree trunks. The Kissing Gourami is the sole member of the family Helostomatidae. The belontiid gouramies, fighting fishes (bettas), and paradise fishes have elongate pelvic fin rays that serve as feelers. Bettas (Siamese Fighting Fish) have been bred to battle like fighting cocks, placing them among the few fishes that have been cultured for purposes other than food, appearance, or research.

Pleuronectiform flatfishes are distinctive, compressed, benthic fishes that have both eyes on the same side of the head. Many flatfishes are important commercially (e.g., dab, flounders, halibuts, plaice, sole, tonguefishes, turbot, and whiffs). Paralichthyids include the Summer Flounder and California Halibut, the latter reaching 1.5 m and 30 kg. The pleuronectid righteye flounders include the Atlantic and Pacific halibuts. Pacific Halibuts may live 40 years and attain lengths of 3 m and masses of 200 kg. The fishery for Pacific Halibut in the North Pacific is a well-regulated, sustainable enterprise.

The most advanced bony fishes are in the order Tetraodontiformes, an almost entirely marine order of medium-sized fishes with thick, leathery skin and with scales often

modified into spines or bony plates. In balistoid triggerfishes and filefishes, the long, rigid first dorsal spine is locked erect by an interaction with the shorter, second spine. Ostraciid boxfishes are encased in a triangular or rectangular bony box, with just the fins and caudal peduncle emerging. Puffers and

ocean sunfishes lack true teeth. Instead, the jaw bone has a cutting edge that looks like separated teeth or is fused into a parrot-like beak. Diodontid porcupine fishes inflate their body by filling the stomach with water, a process that also helps erect and interlock their body spines. Tetraodontid puffers concentrate a powerful and potentially fatal toxin, tetrodotoxin, in their viscera, which adds to the allure of eating puffers in licensed Fugu restaurants in Japan. The Ocean Sunfish, *Mola mola*, is one of the world's heaviest fishes at 1000–2000 kg, producing as many as 300 million eggs. All this biomass is supported on a diet of jellyfishes (Figure 17).

Geographic Diversity

Overview

Fishes occur just about everywhere water occurs in its liquid state, is available through most of the year, and remains below 40 °C. A major zoogeographic distinction can be made between marine and freshwater fishes, with substantial overlap occurring where intermediate salinities occur. Many fishes are restricted to pure fresh water (little or no salinity), many are restricted to normal oceanic salinity (about 35 parts per 1000 salt in water), some occur in both habitats at different times of their lives or of the year, and some occur and are even restricted to areas of intermediate salinity, such as estuaries.

In terms of numbers, about 58% of all fishes are marine and 41% live in fresh water, with the remaining 1% moving regularly between the two salinity designations (Figure 18 and Box 2). Among the 13,000 freshwater species, 80% are primary or obligatory freshwater fishes and are intolerant of even moderate salinities. The remaining 20% can tolerate some salinity and hence inhabit upper estuarine areas or can cross through near-shore ocean regions to move from one river

Figure 18 The global biodiversity of marine, diadromous, and freshwater fishes. Approximate numbers of species are given for each habitat type and its subdivisions.

Box 2 Why are there so many freshwater fishes?

The high global diversity of freshwater fishes (**Figure 18**) is at first surprising. Fresh waters make up only about 0.009% of the earth's water, which means that almost half of all fish species live in less than 1% of the world's water. This 7,500-fold discrepancy in biodiversity per unit volume is probably best explained by the relative productivity and isolation of freshwater bodies. Most freshwater habitats are relatively shallow and receive ample sunlight as well as nutrients running off from adjacent land. Hence freshwater habitats are relatively productive and capable of sustaining abundant life. Most of the ocean, in contrast, is deep, dark, and nutrient-poor. Given that 81% of marine diversity occurs in shallow regions, a relationship between water depth and diversity in fresh waters is not surprising. Adding to the influence of available food is the comparative isolation of most freshwater habitats. Lakes are often created and affected by climatic and geologic forces (e.g., drought, floods, landslides, earthquakes, uplifts) that separate them from other systems. Every lake then can be relatively isolated from other lakes, which means that genetically distinct populations can evolve into new species and that little genetic mixing occurs between lakes. Small streams are separated from each other by larger rivers which are barriers to the movement of small fishes, and large rivers are separated by oceans. As a result, freshwater habitats are perfect habitats for the speciation process. Oceans in contrast are largely continuous habitats that are connected by currents, and ocean fishes typically produce larvae that float for several weeks or months on these currents. Hence genetic exchange is common and opportunities for speciation are not as great. Oceanic basins have relatively distinct faunas, but connectedness within basins discourages the kind of genetic isolation needed for speciation of the sort seen in lakes and rivers.

basin to another. Among the 19,000 marine fishes, the vast majority (69%) live in shallow, warm areas such as coral reefs. The remaining marine species are divided fairly evenly among shallow, cold, deep, open-ocean, and deep-bottom areas (about 10%–15% each). About 2% of marine fishes live in near-surface, open-sea (pelagic) habitats. The approximately 160 diadromous species that live in different salinity regions at different times of their lives are divided among three groups. Anadromous fishes (54%) live most of their lives in the ocean but then migrate to fresh water to spawn; this group includes lampreys, sturgeons, shad, and salmon. Catadromous fishes (25%) spend most of their lives in fresh water and migrate to the sea to spawn; included here are freshwater eels, mullets, and temperate basses. Amphidromous fishes (21%) move between fresh and salt water, but migration to the spawning habitat occurs long before the fishes actually spawn; examples include gobies, sleepers, and galaxiids.

Freshwater Diversity

The world's freshwater habitats occur in six major zoogeographic regions or realms that correspond approximately to continental distributions, with important exceptions. Each region has a fairly distinct fish fauna (again with some exceptions and shared elements) (Berra, 2007).

The Nearctic Region

The Nearctic region consists of subtropical, tropical, temperate, and arctic North America. The region stretches from the Mexican Plateau to northern Canada and Alaska. The Nearctic contains 14 families of primary freshwater fishes, with about 1000 species. The most diverse families are minnows, suckers, North American catfishes, perches (and darters), and sunfishes. Other important families include the lampreys, gars, salmon (many of which are anadromous), and whitefishes; sculpins, which are freshwater species in a primarily marine family (=marine derivatives); pickerels and mudminnows; killifishes; and livebearers. The Nearctic is further subdivided into three subregions: the Arctic–Atlantic (with six provinces), the Pacific (with seven provinces), and the Mexican Transition subdivision. Eleven major river systems drain the region; major lakes are abundant, the largest being the five Laurentian Great Lakes (Ontario, Erie, Huron, Michigan, and Superior).

The Neotropical Region

The Neotropical region contains South America and Middle America. It is the most speciose region of the world in terms of freshwater fishes, with 32 families and more than 4500 species. Particularly diverse groups include the colorful characiforms (1500 species of tetras, piranhas, characins, and freshwater hatchet fishes), 14 families and 2500 species of catfishes, 5 families and 134 species of gymnotiform South American electric knifefishes, and more than 150 species of cichlids. Several secondary freshwater and marine derivative groups are included: freshwater stingrays, herrings, silversides, needlefishes, killifishes, and croakers. Many species remain to be discovered and described, particularly in South America. The Neotropical region has been further divided into eight subdivisions with fairly distinctive faunas. Eight major river systems drain the region; major lakes include Lake Titicaca, the world's highest fish-containing lake.

The Palearctic Region

The Palearctic region encompasses Eurasia, including Europe, northern Africa, and Asia north of the Oriental region. Twenty-seven families and about 600 species of temperate freshwater fishes occur in the region, dominated by minnows and loaches but also perches, pickerels, sturgeons, salmon, sculpins (including the Lake Baikal endemics), and 10 species of catfishes in four families. Endemism increases to the south, as is also the case in the Nearctic region (Kottelat and Freyhof, 2007). The Palearctic and Nearctic regions share numerous families and genera (sturgeons, paddlefishes, minnows, smelts, salmon, pikes, mudminnows, and perches) but only a few species occur in both (i.e., Northern Pike, Longnose Sucker, Burbot, Threespine Stickleback, and Fourhorn Sculpin). The region is sometimes subdivided into six subregions based on faunal groupings. Ten major river systems drain the region; major lakes include the Black and Caspian Seas and Lake Baikal, the world's oldest and deepest lake.

The African or Ethiopian Region

The African or Ethiopian region is second to the Neotropics in freshwater fish diversity, with 36 families and more than 2000 species of primary and secondary freshwater fishes. The African region includes all the African continent south of the Sahara Desert, plus the large island of Madagascar

with its endemic fauna. Half of the fishes are in the superorder Ostariophysi, including 300 minnows, 190 characiforms, and 360 catfishes in six families. Other diverse groups include killifishes and topminnows, elephantfishes and other osteoglossiforms, and cichlids. As many as 1000 cichlid fishes may occur in the three African Great Lakes of Lake Victoria, Lake Tanganyika, and Lake Malawi, with more cichlids in smaller surrounding lakes and rivers (see **Figure 16**). Four lungfishes and all 11 polypteriform bichirs occur in Africa. Ten to 12 zoogeographic provinces are recognized, with six major river drainages and numerous lakes including the African Great Lakes of Victoria, Malawi, and Tanganyika.

The Oriental Region

The Oriental region includes eastern Iran, India and Sri Lanka, China south of the Yangtze River, Southeast Asia, and the large island regions of Taiwan, the Philippines, and the East Indies/Indo-Malayan Archipelago. The Oriental region contains 43 families of primary and secondary freshwater fishes. Most diverse are the minnows, loaches, and 12 families of catfishes; clariid walking catfishes and bagrid catfishes are particularly diverse. Other important groups include algae eaters, river loaches, snakeheads, spiny eels, labyrinth fishes and gouramis, a few cichlids, and archerfishes. The Oriental region shares many families with the Palearctic to the north and the Ethiopian to the west but shares few families with the Australian region to the southeast. The Oriental is often subdivided into two major subregions: Peninsular India with more than 700 species and Southeast Asia with more than 1000 species. Each subregion has two major river drainage systems; large lakes are uncommon. Southeast Asia is sometimes divided further into five zoogeographic regions.

The Australian Region

The Australian region (New Guinea, Australia, New Zealand, and Oceania) is relatively depauperate in true freshwater fishes, and in fact all but three of the freshwater fishes in the region are members of families obviously derived from marine groups. The northwestern border of the region, and the practical limit of primary freshwater fishes, is dramatically delineated by an ocean boundary that lies southeast of Java, Borneo, and Sulawesi and is known as Wallace's or Weber's Line. Nineteen families and about 210 species occur primarily in fresh water in the region, but only the Australian lungfish and two species of bonytongue saratogas are true freshwater fishes (another 33 families and 150 species of marine fishes frequently enter fresh waters in Australia). Other important families, many with species endemic to specific regions, include lampreys, river eels, herrings, two families of catfishes, southern smelts and graylings, Salamander fish and other galaxiids, silversides, rainbow fishes, Barramundi, grunters, glassfishes, temperate perches or basses, sleepers and gobies, and Torrentfish (in New Zealand). One major river system occurs on New Guinea (the Fly) and two on Australia (Darling and Murray); permanent, large lakes are rare.

Marine Diversity

Delimiting zoogeographic regions in the world's oceans is complicated by depth, currents, and geographic locales; different faunal breaks occur depending on near-shore, pelagic, or deepsea environments. The greatest fish diversity and the greatest geographic differentiation occur in near-shore, continental shelf (to about 100 m depth) regions. These regions are separated by continents, by large expanses of open ocean, and by currents that differ in temperature from that of the region in question. Temperature zones divide the seas into tropical, temperate, boreal, and polar regions. In addition, different faunal groupings apply to pelagic fishes and to fishes of the deep sea (Briggs, 1995).

The Indo-West Pacific Region

The Indo-West Pacific region includes shallow tropical seas that extend from South Africa and the Red Sea eastwards through the Indo-Malayan area and Australia to Hawaii and Easter Island; it also includes Micronesia, Melanesia, and Polynesia. The Indo-West Pacific is by far the most species-rich marine area, containing 3000–4000 tropical fish species. It is similarly diverse in sea snakes and many invertebrate taxa such as reef-building and soft corals, mollusks, tube worms, and echinoderms, although these numbers describe life in the upper 50–75 m of the reef that are accessible to scuba divers. As new exploration technologies allow deeper exploration, hundreds more fish species have been discovered. Regardless, the Indo-West Pacific is considered the center of evolution for many of the common coral reef fish families that occur in other tropical regions. Only a few families are endemic to the Indo-West Pacific (e.g., sillaginid whittings and rabbitfishes). Common families include moray eels, squirrelfishes, sea basses, grunts, snappers, cardinalfishes, butterflyfishes, angelfishes, damselfishes, wrasses, parrotfishes, surgeonfishes, gobies, triggerfishes, and boxfishes. Barriers to movement of Indo-West Pacific fishes are cool waters to the north and south and a vast expanse of open, deep water to the east known as the Eastern Pacific Barrier. Eight different provinces have been recognized in the Indo-West Pacific, separating it into a huge Indo-Polynesian region and seven smaller areas.

The Eastern Pacific Region

The Eastern Pacific region, with approximately 800 fish species, runs from southern Baja California to Ecuador, its northern and southern limits defined by the coldwater California and Peru currents. Despite its location in the Pacific Ocean, the Eastern Pacific is faunistically more similar to the tropical Atlantic, containing many species that are almost indistinguishable from Atlantic forms. The two oceans mixed before the Panamanian Isthmus formed and the two areas still share 12 species, despite 3 million years of physical separation. Most families are less diverse here than in the Western Atlantic, with the exceptions of sea catfishes, croakers, and herrings. Dactyloscopid sand stargazers occur here and in the Atlantic, but not in the Indo-West Pacific. Sixty-two Indo-West Pacific species have managed to cross the Eastern Pacific Barrier. Three provinces – Mexican, Panamanian, and Galapagos – are recognized.

The Western Atlantic Region

The Western Atlantic region is the second most diverse oceanic area, containing 1200 fish species. It includes Bermuda (which, although at 32° N, sits in the tropical Gulf Stream), southern Florida, the Bahamas Bank, the Caribbean Sea, and tropical and temperate portions of South America. Most of the families that occur in the Indo–West Pacific also occur in the Western Atlantic; a few families are more diverse here, such as grunts and toadfishes. Strong currents of warm water separate the Western Atlantic fauna from colder waters along much of its boundaries. It is subdivided into Caribbean, Brazilian, and West Indian provinces.

The Eastern Atlantic Region

The Eastern Atlantic region is a relatively small area along the west coast of Africa from Senegal to Angola and extending out to oceanic islands such as Ascension and St. Helena. Tropical marine fishes here are limited by cool-water currents impinging from both the north and the south as well as by substantial freshwater runoff and sediments from several major west African rivers, all factors that discourage coral reef growth. The region contains “only” 500 shore fishes; most coral reef families occur but are represented by only a few species. Porgies are particularly diverse. No subdivisions are recognized, with the possible exception of the warm-temperate Mediterranean. The Mediterranean Sea contains 540 species, with many species in the same families as those in the Eastern Atlantic. The Mediterranean has the dubious distinction of being the most heavily invaded tropical marine area in the world, with at least 52 alien fish species having moved in from the Red Sea (an Indo–West Pacific subregion) via the human-made Suez Canal.

The Arctic Region

The Arctic region encompasses high-latitude (above 60° N) waters of both the Pacific and Atlantic Oceans. It reaches from Nunivak Island, Alaska, northward and across the polar region to Newfoundland and Norway in the northern Atlantic. Of the two polar areas, the Arctic is more diverse. Successful groups include skates, herrings, salmon, smelts, cods, eelpouts, greenlings, sculpins, poachers, snailfishes, pricklybacks, wolf-fishes, gunnels, and righteye flounders. Diversity within many of these groups is greater in the Pacific than in the Atlantic portions of the region. A total of 415 species occur here. Distribution of many of these families appears to be limited by temperature, with warmer waters and currents to the south determining species’ boundaries.

The Antarctic Region

The Antarctic region (above 60° S) has its own distinctive fauna that is restricted to Antarctic waters and the surrounding Southern Ocean, including the cold waters of Australia, New Zealand, and nearby oceanic islands. Forty-nine families and 274 species occur here, 13 families and 174 species of which are identified as Antarctic continent species. A particularly successful group is the notothenioid icefishes and relatives, which account for 55% of Antarctic species. Families include bovicthyids, cod and crocodile icefishes, plunderfishes, and dragonfishes. Non-notothenioids include skates, snailfishes,

eelpouts, lantern fishes, eel cods, deepsea cods, and southern flounders.

Temperate Regions

To the north of the Indo–West Pacific lie cooler temperate waters with their own characteristic fish faunas. This area can be divided into four fairly distinct regions according to location and temperature: Japanese warm-temperate and Californian warm-temperate regions and Eastern and Western boreal regions. The warm-temperate areas (from about Hong Kong to Tokyo in the west and from lower Baja California to central California in the east) contain a fauna that fluctuates seasonally, as tropical species move north in the summer and boreal species move south in the winter. Notable families to the west include lizardfishes, flyingfishes, mullets, jacks, sea basses, and croakers and to the east include endemic silversides, sea basses, croakers, damselfishes, wrasses, and flatfishes (Figure 19). The more northerly boreal regions (approximately north from central California in the east and Korea in the west) contain similar families but different species. Important families include migratory salmonids, sculpins, rockfishes, snailfishes, greenlings, gunnels, pricklybacks, and righteye flounders. In the southern Pacific, coldwater currents create at least three temperate faunal regions, with centers of distribution around Australia, New Zealand, and South America.

In the Atlantic, three northern temperate areas occur: the western and eastern Atlantic boreal regions and the Atlantic warm-temperate or Carolinian region. The boreal regions (Newfoundland to Cape Hatteras in the west and British Isles

Figure 19 The garibaldi, *Hypsypops rubicundus*, is a temperate member of the otherwise largely tropical family of pomacentrid damselfishes. It is common in kelp beds of southern California and is the state marine fish.

to northern Europe and Scandinavia in the east) share a fauna of salmonids, cods, sticklebacks, poachers, sculpins, wolf-fishes, and righteyed flounders, with occasional strays from more southerly waters during warm months. The Carolinian extends from Cape Hatteras south to Florida and also to the Gulf of Mexico, with southern Florida housing tropical species. Common groups are clupeids, sea robins, pipefishes, silversides, needlefishes, killifishes, croakers, lefteyed flounders, and puffers. Temperate faunas also occur in the southern Atlantic, but their areas and diversity are less than those of the southern temperate faunas of the Pacific Ocean. Two recognized regions are the eastern South American and southern African warm-temperate regions. The former region's fauna includes sea catfishes, croakers, herrings, gobies, scorpionfishes, and sea basses; the latter area has many colder water members of Indo-West Pacific families.

Pelagic Regions

The 350 species of pelagic fishes occur in ocean surface waters to a depth of 200 m. This habitat type can be divided into 10 different regions based on faunal differences, with more joining of Southern Hemisphere areas because of the relative lack of large land masses. These regions are Arctic and Antarctic polar, North Pacific cold temperate, North Pacific warm-temperate, tropical Indo-Pacific, North Atlantic boreal, North Atlantic warm-temperate, Atlantic tropical, southern warm-temperate, and southern cold temperate. Many of the world's most important fisheries species occur in pelagic regions, including numerous sharks, sardines and herrings, salmon, codfishes, pollocks, hakes, haddocks, sauries, mackerels, and tunas. In addition, about 100 species of mostly pelagic fishes have a worldwide distribution. This group includes pelagic sharks (White, Whale, Tiger, and perhaps Megamouth), Swordfish, and ocean sunfishes.

The Deep Sea

Waters deeper than 200 m are as much a zoogeographic as a habitat entity. The deepsea is generally divided into three

major regions based on depth: the open-water mesopelagic (200–1000 m) and bathypelagic (1000–4000 m) regions and the bottom-associated benthal (200–1000 m) region. Benthal fishes are further divided into benthopelagic fishes that hover just above the bottom and benthic fishes that rest in contact with the bottom. Deepsea fishes are most common in these regions between 40° N and 40° S latitude, approximately between San Francisco and Melbourne in the Pacific and between New York City and the Cape of Good Hope in the Atlantic. Abyssal and hadal (trench) regions deeper than 4000 m are relatively depauperate.

Each region has a characteristic and relatively diverse bony fish fauna consisting of fishes from many different taxonomic groups. The mesopelagic region worldwide contains about 750 species in seven different superorders and nine orders. Despite their lack of relatedness, deepsea fishes share many anatomical and physiological features, suggesting independent, convergent evolution of adaptations to deepwater existence. Mesopelagic fishes typically have photophores (light organs) on their silvery bodies; have relatively large, oftentubular eyes; undergo daily migrations to surface waters to feed at night; and have large mouths and long teeth. Common names of mesopelagic fishes reflect these traits: barreleyes, bristlemouths, dragonfishes, sabertoothfishes, lanternfishes, tubeeyes, and swallowers.

The bathypelagic region is the largest habitat space on the earth, accounting for 88% of oceanic volume. The five superorders, nine orders, and 200 species in the cold, dark bathypelagic region share some traits with mesopelagic fishes but possess them in the extreme. Photophores are concentrated on lures used to attract prey; eyes are often small; mouths are extremely large and teeth very long; stomachs are expandable; bodies are black; and body musculature, bones, and scales are greatly reduced. These traits reflect greater habitat space and increasingly rare feeding opportunities with increasing depth, which select for an increasing need to conserve energy and to be able to take advantage of feeding opportunities. Again, bathypelagic fishes have names indicative of their adaptations: sawtooth eels, gulper eels, swallower

Figure 20 A 15-cm long female Wolftrap Anglerfish, *Lasiognathus amphirhamphus*. Anglerfishes are among the more diverse groups in the bathypelagic region. Many anglerfishes possess a lure at the tip of their modified first dorsal spine used to bring prey within striking distance of a large, expandable mouth. Photo courtesy of Pietsch TW.

eels, dragonfishes, anglerfishes, seadevils, and fangtooths (Figure 20. Anglerfish).

Benthic fishes include about 1000 bony fish species in four superorders and nine orders, plus chimaeras and squaloid sharks. Different families inhabit bottom compared to open-water regions. Benthic fishes include greeneyes, tripodfishes, hakes, grenadiers, cuskeels, batfishes, snailfishes, and eelpouts. Although diversity decreases below 1000 m, grenadiers and rattails live between 1000 and 4000 m, tripodfish have been found to 6000 m and snailfishes to 7000 m, and some cuskeels have been found as deep as 8000 m.

Although some differences in species composition occur in different ocean basins or in association with different water masses, deepsea species are relatively cosmopolitan, occurring in several different oceans. One trend is for fishes to occur deeper at lower latitudes, such that species that are bathypelagic near the equator may be mesopelagic at middle latitudes and even epipelagic at the poles.

Mammals (Pre-Quaternary), Extinctions of

William A Clemens, University of California, Berkeley, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Background extinction Rates of extinction that characterized the major part of the evolution of life.

Clade A group of organisms including its common ancestor and all its descendants.

Crown group A clade including a group of modern species, the common ancestor, and all its descendants, including extinct lineages.

Extinction The termination of a lineage of organisms.

Mass extinction A short period of Earth history in which the rate of extinction reached an exceptional high level.

Paraphyletic A group of organisms that includes the common ancestor but not all of its descendants.

Mammals and Other Synapsids

The evolutionary history of synapsids, which includes mammals and their ancestors, began with the origin of the group in the Carboniferous Period approximately 359–299 million years ago (Ma) (Table 1). Prior to this interval, terrestrial vertebrates underwent their first evolutionary radiation. One of these lineages, characterized by a specialized type of egg (the amniote egg), split into at least two clades: reptiles (including birds) and synapsids (including nonmammalian synapsids and crown group mammals; Figure 1). Early members of these clades can be distinguished by different structural patterns of the posterior parts of their skulls. Clearly, part of the ancestry of mammals, early nonmammalian

synapsids, lacked specialized features of skull structure that characterize members of the crown group Mammalia – for example, only one pair of bones (the dentaries) making up the lower jaw or the presence of three bones (malleus, incus, and stapes) in the middle ear. Direct evidence is not preserved in the fossil record, but it is probable that these early synapsids lacked hair, mammary glands in the females, and endothermy – traits commonly used to distinguish modern mammals from reptiles.

Unfortunately, in many older and some recent texts, early synapsids are referred to as mammal-like reptiles. These early

synapsids definitely were not members of the ancestry of reptiles. Morphological similarities to reptiles are the product of inheritance and retention of traits found in their common ancestor. In the following discussion, these early synapsids will be dubbed nonmammalian synapsids, which accurately expresses the fact that they were members of the early part, the stem, of the synapsid clade but not members of the crown group Mammalia (Figure 1).

In a broad-brush summary, the evolutionary history of the synapsids can be divided into three phases. Beginning in the Carboniferous, the first evolutionary radiation of nonmammalian synapsids was interrupted by the mass extinction event used to mark the Permian–Triassic boundary. The surviving lineages of nonmammalian synapsids radiated again but did not regain their position as a dominant group of terrestrial vertebrates. Prior to or during the next mass extinction, probably soon before the Triassic–Jurassic boundary (approximately 201.6 Ma), almost all lineages of nonmammalian synapsids became extinct. The few surviving lineages were made up of animals of small body size, sizes equivalent to those of modern mice or shrews. The following Jurassic and Cretaceous Periods, which lasted from approximately 201.6–65.5 Ma, constituted the Age of Dinosaurs. This interval witnessed a major evolutionary radiation that included the origin of the crown group Mammalia. The Cretaceous ended with another mass extinction event; this was the time of extinction of dinosaurs other than birds. During the following Tertiary Period (65.5–2.8 Ma), mammals flourished and their diversity rapidly increased. Biogeographic differentiation, extinction events, and periods of faunal turnover complicated Tertiary evolutionary radiations of mammals.

Patterns and Causes of Extinctions

Although discussed in more detail later, a few issues relating to the nature and causal factors of extinctions need to be reviewed here as the background for analysis of the role of pre-Quaternary extinctions in shaping the course of mammalian evolution.

Extinctions and Pseudoextinctions

In any attempt to assess changes in biodiversity resulting from extinctions, care must be taken to differentiate between true, biological extinctions, and what have been termed as pseudoextinctions. In a biological sense, extinction is the termination of the group or groups of organisms comprising a species. No longer was there successful reproduction and survival of the young to sexual maturity, population size dwindled to zero, and the species, as well as the lineage it represented, was lost from the biota.

Pseudoextinction refers to an artifact produced by zoological nomenclature; a named unit becomes extinct but the lineage it represents survives. The taxonomy (the system of recognition and naming of groups of organisms) of the Equidae, the family that includes modern horses, asses, and zebras, provides many examples of pseudoextinction. The oldest known species of the family are a group of lineages

included in the genus *Hyracotherium* (= *Eohippus*). These were diminutive, multitoed inhabitants of tropical forests. The fossil record documents increase in body size, loss of toes, and other significant morphological changes in descendants of *Hyracotherium* – for example, *Orohippus*, *Miohippus*, *Merchyhippus*, and *Dinohippus*. These extinct genera are the members of the ancestry of modern horses, zebras, asses, and other closely related species, all of which are included in the genus *Equus*.

The genus *Hyracotherium* is composed of the common ancestor of all the species referred to as *Hyracotherium* including the lineage leading to *Orohippus* the next member of the Equid family tree. In the jargon of modern taxonomy, *Hyracotherium* is paraphyletic, a unit that includes its common ancestor and some, but not all, of the common ancestor's descendants. All genera of the family tree ancestral to *Equus* are now extinct. The extinctions of these paraphyletic groups, however, did not mark the termination of the equid lineage; they are products of the system of recognizing and naming organisms. (To highlight their status, the names of paraphyletic groups are often enclosed in quotation marks.)

It also must be stressed that in most studies of pre-Quaternary extinctions, species are not the basic units considered. Usually these studies analyze the differences in numbers of genera or families, a procedure that opens the possibility of significantly muting patterns of change in biodiversity. For example, if a genus consists of only one species, loss of the species also results in the loss of the genus. However, if the genus contains many species, the loss of one species is not reflected at the generic level. Thus, a major extinction event that resulted in the loss of 60% of the species extant in a region might be reflected in the loss of only 30% of the genera or 10% of the families represented.

Background and Mass Extinctions

Since the origin of life approximately 3.5 billion years ago, extinction has been a major process influencing the course of its evolution. Current estimates from the fossil record indicate that more than 90% of the species that once existed are now extinct; some suggest that the number is more than 99%. Modern studies of the patterns of extinction have their roots in the analyses of the times of origin and extinction of families and genera of marine invertebrates, particularly those carried out by Sepkoski, Raup, and their associates (Raup, 1991). These studies and prior research indicated that the rates of extinction fall into two categories, background extinctions and mass extinctions. Background extinction rates appear to characterize the majority of the history of life. Several times during the past 600 Ma, however, rates of extinction increased greatly over short periods of geological time. Taxa that were not particularly closely related and inhabited diverse areas of the oceans became extinct. These events were recognized as mass extinctions. The most severe of the mass extinction events are identified as the "Big Five" mass extinctions.

Although the available database for evolution of terrestrial vertebrates and plants is not as biogeographically extensive and detailed as the marine record, enough is known to show that some of these mass extinctions modifying the marine

biota were correlated in varying degrees with major changes in the evolution of terrestrial life. In particular, the three most recent mass extinctions marking the Permian–Triassic, Triassic–Jurassic, and Cretaceous–Tertiary boundaries in the marine realm were associated with times of significant modifications in the course of evolution of nonmammalian synapsids and early mammals.

Temporal and Biogeographic Scales of Mass Extinctions

Mass extinctions were defined subjectively as short periods of Earth history during which rates of extinction reached exceptionally high levels in widespread areas. In evolutionary terms, how short is short? In studies of recent extinctions in which events are followed on an ecological timescale, short periods of time are measured in terms of years, decades, centuries, or possibly a millennium or two. A recent compilation of recent estimated durations of the last three of the “Big Five” mass extinctions revealed values as much as 8.3 Ma to as short as less than a year (Barnosky *et al.*, 2011).

Current radiometric methods for determining ages and durations of pre-Quaternary events lack the degree of resolution found in ecological studies of the modern biota. For example, using the $^{40}\text{Ar}/^{39}\text{Ar}$ method of age determination, which is one of the most precise methods of radiometric age determination available for pre-Quaternary deposits, the age of the Cretaceous–Tertiary boundary, as recognized in nonmarine sediments in eastern Montana, is placed at 65.58 ± 0.04 Ma (Wilson, 2005). As data on extinctions of Cretaceous lineages of nonmarine and marine organisms are collected and correlated, all extinction events that occurred within an interval of 80,000 years would necessarily be treated as having occurred simultaneously. Recognition of the role of short-term modifications of the biota on an ecological timescale and their consequences in terms of background and mass extinctions on a geological timescale remains a major challenge.

In comparison to the fossil record of marine invertebrates, which is the foundation for studies of the role of mass extinctions in evolution, the fossil record of terrestrial vertebrates is much more limited, particularly in its biogeographic coverage. For example, detailed records of mammalian evolution across the Cretaceous–Tertiary boundary are limited to sites in the Western Interior of North America (Archibald, 2011). Significant gaps in the fossil records of mammalian evolution in Eurasia and the continents of the Southern Hemisphere characterize this interval. One consequence of these gaps is the uncertainty in determining the origins of mammalian groups that appear soon after a mass extinction event. Were they descendants of a few local survivors or immigrants from another less impacted and yet to be sampled area?

Distal and Proximal Causal Factors

In studies of extinction, a distinction must be made between distal and proximal causal factors. Proximal causal factors are those that impinge directly on individuals and are the immediate causes of their death. Distal causal factors are the

regional or global events that result in changes in local (proximal) biological and physical environments affecting individual organisms. In the much longer period of mammalian evolution before the Quaternary, several distal causal factors emerge as major contributory factors to mass extinctions and other significant changes in the course of evolution of the group.

Recognition of some distal causal factors can be traced to the development of our understanding of plate tectonics and the mechanisms involved in movements and changes in configurations of continents and oceanic basins. Among the immediate consequences of modification of the configuration of these basins are changes in their coastlines. Hallam and Wignall (1997) and other workers noted that many of the major mass extinctions were associated with times of withdrawal of shallow continental seas (marine regressions) and reduction of coastal habitats. Additionally, changes in patterns and strengths of oceanic currents coupled with changes in continental topography contributed to modification in global climates. Another product of the changes in configurations of continents during periods of marine regression was the establishment of terrestrial connections between long-isolated continents. For example, the intermittent formation of dry land connections between Siberia and Alaska at various times during the Mesozoic and Tertiary facilitated mammalian dispersal and probably contributed to mammalian extinctions through some combination of competition, predation, and possibly introduction of new diseases.

Volcanic activity has played and continues to play a significant role in modifying the earth's environments. Major eruptions produce large quantities of particulate matter, aerosols, and acids. These clouds can reach magnitudes sufficient to limit or block the sun's radiation from reaching the surface of the earth, causing a decrease in temperature. Later, they would trap heat radiated from the surface to produce a greenhouse warming of the climate. Increased amounts of acid rain also are predictable consequences of volcanic activity. Late in the Cretaceous, high levels of volcanic activity resulting in the formation of the Deccan Traps in India have been hypothesized as a distal causal factor of the mass extinction at the end of the Period.

Although the hypothesis had precursors in earlier decades, the assertion by Alvarez *et al.* (1980) that the impact of an asteroid was the causal factor of the Cretaceous–Tertiary mass extinction focused attention on the potential role of extra-terrestrial bombardment in controlling the course of evolution of the earth's biota. Their initial hypothesis argued that the impact of an asteroid was the distal cause of the extinction of nonavian dinosaurs and numerous other kinds of terrestrial and marine organisms. The hypothesized proximal causes were the formation of dust clouds that first produced global refrigeration by blocking solar energy and then a greenhouse effect by trapping heat in the atmosphere. Impact-generated global acid rain and wildfires also were suggested as contributory factors, but the severity and even the occurrence of both has been challenged by recent research.

It has been argued that a mass extinction is an exceptional event, and therefore, requires an exceptional causal factor. Two aspects of this assertion require comment. The level of ecological interdependence of members of the terrestrial biota

has, no doubt, varied through time. Terrestrial ecosystems characterized by relatively low levels of interdependence of their members might well be able to withstand the loss of one or a few species. In contrast, ecosystems with highly interdependent members might not be able to withstand the loss of one or a few species, resulting in the collapse of the whole system and consequent extinction of many other species. Thus, a period of global warming, for example, could have a catastrophic effect on highly interdependent ecosystems, but causes little or no change in those that were characterized by a lower level of interdependence.

Secondly discussions of the causal factors of mass extinctions have too often been simplified into debates favoring one factor, marine regressions of the seas, outbursts of volcanic activity, or impacts of large extraterrestrial bodies, and discounting the effects of the others. Analyses of the geological and fossil records of the Mesozoic and Cenozoic by Arens and West (2008) revealed that the highest frequency of intervals with elevated extinction were found when high levels of volcanic activity producing extensive flood basalts and impacts coincided. Building on the work of community ecologists and other paleontologists, for example, Erwin (2001), they argued that high levels of volcanic activity or climatic change have produced long-term modifications in community structure, the press disturbances. In contrast, pulse disturbances were short-term events that produced abrupt modifications of community structure and may be associated with significant mortality. They hypothesize that episodes of mass extinction probably are not attributable to a single cause, but were the consequences of combinations of press and pulse disturbances.

Finally, the focus of this article is on extinctions of lineages and their effects on patterns of evolution and diversity. Extinction is but one-half of the equation for calculating changes in biodiversity. Variation in the rate of origination of new species can have a marked effect on biodiversity. For example, analysis of the fossil record of nonavian dinosaurs during the Jurassic and Cretaceous shows that they evolved rapidly; a genus of nonavian dinosaur rarely lasted for more than a geological stage (on average 6 Ma in duration) or two. Throughout most of their history, rates of extinction and origination of nonavian dinosaurs were high. In the last two stages prior to their extinction at the end of the Cretaceous, a high rate of extinction of genera appears to have been maintained, but the rate of origination of new genera was depressed.

Origin of Synapsids and the Permian–Triassic Mass Extinction

During the Carboniferous Period (Table 1), approximately 359–299 Ma, the reptilian and synapsid clades differentiated. From this beginning, the first phase of synapsid evolution, characterized by their prominent position in terrestrial faunas, would last until near the end of the Triassic. It was interrupted, and the course of synapsid evolution altered, by the massive extinctions that marked the Permian–Triassic boundary.

In the Late Carboniferous and Early Permian, basal non-mammalian synapsids, the pelycosaurs, were the most diverse

terrestrial vertebrates but initially limited to the hot, wet environments of the equatorial coal swamps. The pelycosaur-dominated terrestrial faunas of the Late Carboniferous were composed of many more carnivores than herbivores; at first glance, this appears to be an ecologically anomalous situation. It is now thought that the dominance of carnivores is not a product of a bias in preservation or collecting, but reflects an initial stage in the evolution of a terrestrial vertebrate ecosystem. Many of the species of these early nonmammalian synapsids may well have been amphibious, returning to streams and lakes to feed on fish and freshwater invertebrates.

Gradual changes in the climate during the Early Permian resulted in the development of drier, seasonally arid areas. At first, terrestrial herbivorous pelycosaurs became more abundant as a fully terrestrial vertebrate ecosystem evolved. Then, about the beginning of the Late Permian, a rapid radiation of therapsids began (Figure 1). This radiation produced a variety of carnivorous and herbivorous forms, including the abundant dicynodonts. It occurred during a time of gradually changing climate and flora. The expansion of the biogeographic range of the therapsids beyond equatorial regions and decline in the diversity of pelycosaurs add to the evidence suggesting that the diversification of therapsids was related to the evolution of fully terrestrial ecosystems well before the end of the Permian (Kemp, 2005).

The mass extinction used to mark the end of the Permian was the most severe yet recorded. It has been estimated that more than 90% of the species and 50% of the families of marine invertebrates were lost during this event. Terrestrial ecosystems of the Late Permian were made up of a variety of therapsids as well as a few lineages of reptiles and amphibians. These too were greatly decimated. Of the approximately 50 families of terrestrial vertebrates present in the last 5 Ma of the Permian, approximately 75% died out. This dramatic loss included large and small herbivores and carnivores. Notable survivors among the nonmammalian synapsids were a few lineages of carnivorous therapsids and the herbivorous dicynodont, *Lystrosaurus*.

The debate continues over the causal factors of the mass extinction marking the end of the Permian (Benton *et al.*, 2003). A variety of lines of evidence suggest that this was a time of global warming, probably related to a marine regression followed by development of anoxic oceans. Extensive volcanic activity, the eruption of the massive flood basalts of western Siberia, was another distal causal factor. This was also a time of elevated concentrations of CO₂ and H₂S in the atmosphere. Currently, students of the Permian–Triassic mass extinction appear to favor some combination of changes in the oceans and volcanic activity as its distal causal factors. No convincing evidence of the impact of an asteroid or other extraterrestrial body has been discovered.

The Second Therapsid Radiation and Late Triassic Faunal Turnover

As a result of the decimation caused by the Permian–Triassic mass extinction, the taxonomic diversity of the earliest Triassic terrestrial faunas was greatly reduced. These faunas were dominated by a dicynodont, *Lystrosaurus*, but included

representatives of a few other lineages of nonmammalian synapsids, which were the basal stocks of another but lesser evolutionary radiation. Later, in the Early Triassic, large and small herbivorous forms, primarily dicynodonts, became prominent elements of terrestrial faunas. In parallel, the surviving carnivorous therapsids radiated, producing a variety of new lineages of large and small carnivores as well as some herbivorous species. In comparison to Permian terrestrial faunas, synapsids did not regain their dominant position in Triassic terrestrial vertebrate faunas.

Analysis of the evolutionary radiation of the carnivorous therapsids during the Triassic reveals trends in modification of skull structure and morphology of the postcranial skeleton that increasingly came to resemble those characterizing modern mammals (Kemp, 2005). For example, the lower jaw was modified through expansion of the dentary bone and the reduction or losses of other bones characteristic of early synapsid or reptilian jaw structure. These were preliminary steps toward acquisition of an articulation of the dentary bone of the jaw with the squamosal bone of the skull, a key skeletal character for distinguishing modern mammals from reptiles. Limb posture began to be modified from a primitive, sprawling stance to a more typically mammalian stance with the elbow and knee tucked close to the body and the limbs brought into an upright posture.

A few million years before the end of the Triassic, some synapsids evolved a functional articulation between the dentary and squamosal. Many textbooks and popular articles present the acquisition of this structure as the hallmark of the Mammalia and identify the end of the Triassic (approximately 251 Ma) as the time of origin of the group. In current phylogenetic classifications, however, the clade Mammalia is restricted to a crown group including the common ancestor of monotremes (the echidna and platypus), marsupials, and placentals and all its descendants. Phylogenetically, some of the very advanced nonmammalian synapsids with a dentary–squamosal jaw articulation and other mammal-like specializations lie outside the crown group; they are sister lineages. In many recent research papers, these very advanced nonmammalian synapsids are referred to as mammaliaforms.

During the Late Triassic, the composition of terrestrial faunas underwent a major change that played a significant role in reshaping the courses of evolution of synapsids and other vertebrates. All the lineages of Triassic synapsids, except for a few lineages of mammaliaforms and one group of herbivorous nonmammalian synapsids, the tritylodonts, became extinct by the end of the Triassic. All the surviving lineages were represented by species of relatively small body size. During this interval two groups of reptiles, the rhynchosaurs and later several lineages of dinosaurs became the dominant terrestrial vertebrates.

Identification of the causal factors behind the Late Triassic decline of therapsids and the contemporaneous increasing diversity of dinosaurs as well as the mass extinctions in both the marine and terrestrial realms marking the end of the Triassic continues to be a matter of debate. It has been argued that the early dinosaurs were in some way competitively superior in their interactions with the therapsids and this was the cause of extinction of these lineages. More likely, the decline in

diversity and demise of some therapsid lineages in the Late Triassic is attributable to changes in the environment. Taking advantage of the losses of these lineages, dinosaurs radiated opportunistically. Extensive eruptions of flood basalts in rifts developed by the initial separation of North America from Europe and Africa (the Central Atlantic Magmatic Province) and associated modifications of the atmosphere appear to have been distal causal factors of the Triassic–Jurassic boundary mass extinctions.

Mammalian Evolution During the Age of Dinosaurs

During the Jurassic and Cretaceous, popularly dubbed the Age of Dinosaurs, mammaliaforms and early mammals were not dominant members of terrestrial faunas. Functional interpretations of their dentitions suggest that most were probably carnivorous, feasting on small prey including small terrestrial vertebrates and invertebrates. For the most part, they were very small animals, in the size range of modern mice and rats. A few evolved larger body sizes, rivaling modern opossums or raccoons, but these species were exceptions to the rule.

Recent discoveries reveal that in spite of their relatively small size during the Jurassic, mammaliaforms evolved diverse ecomorphological specializations (Luo, 2007). For example, two lineages of closely related mammaliaforms evolved aquatic specializations, one with a beaver-like flattening of their tails and another with an otter-like transverse compression of their tails. Members of another mammaliaform lineage developed folds of skin linking their neck, limbs, and tail to produce membranes resembling those of modern gliding squirrels.

For the most part, these mammaliaform lineages became extinct by the middle of the Cretaceous. One group that appears in the fossil record in the Jurassic, the multituberculates, evolved a remarkably rodent-like style of dental specialization and is interpreted as having been omnivorous or herbivorous in dietary preferences. This interpretation is strengthened by the persistence of the group into the Paleocene of the Northern Hemisphere. Then, in the late Paleocene as rodents began their evolutionary radiation, the taxonomic diversity of multituberculates dwindled. By the end of the Oligocene, when almost all families of rodents had differentiated, multituberculates had become extinct.

Tracing the course of mammalian evolution during this phase of synapsid evolution is complicated by distinct biogeographic differentiation. Unlike the Permian and Triassic, when most of the terrestrial regions of the world were parts of one supercontinent, Pangaea, through the Jurassic and Cretaceous terrestrial areas and their faunas were fragmented. In part, this was the product of plate tectonic processes that broke up the Pangaeian supercontinent and shifted the positions of the resulting continental blocks. Additionally, the Age of Dinosaurs was a time characterized by extensive marine transgressions when shallow seas covered many areas and added to fragmentation of terrestrial areas. By the beginning of the Cretaceous, when the currently sparse fossil record of these faunas gives us our first real picture of biogeographic differentiation, there is evidence of distinct northern (North American–Eurasian) and southern (Australian–Antarctic–South

American) terrestrial faunas. Unfortunately, very little is known of the history of mammaliaform and mammalian evolution in the African continent during this interval.

The Cretaceous also was a time of major changes in the terrestrial biota. Angiosperms made their appearance and began to diversify. First records of most modern families of insects document their diversification. Particularly in the Northern Hemisphere, dinosaurian faunas underwent a major reorganization. Global climates of the Jurassic and Cretaceous were, in general, distinctly warmer and more equable than modern climates. The latitudinal climatic gradient, reflecting the degree of difference between equatorial and polar conditions, was much lower. Throughout most of the interval, there is no evidence of continental glaciations. Finally, to round out this description of the environmental settings of mammalian evolution during the Age of Dinosaurs, it must be noted that evolution of the terrestrial biota was not interrupted by a mass extinction event.

By the middle of the Cretaceous, the mammalian fauna had undergone a major turnover in composition. In the Northern Hemisphere, with the exception of the hardy multituberculates, most of the Jurassic lineages of mammaliaforms had dwindled in taxonomic diversity or became extinct. Currently, the first record of the crown group Mammalia is from the Northern Hemisphere and of Late Jurassic age (Luo *et al.*, 2011). By the Early Cretaceous two of the three surviving lineages of the Mammalia, metatherians (including marsupials) and eutherians (including placentals) had begun to radiate here. Mammalian evolution on a southern continent, composed of the modern Australian, Antarctic, and South America continents, followed a different course. Metatherians and eutherians have yet to be discovered there. The terrestrial fauna included the first records of the third major lineage of the Mammalia, the monotremes. Additionally, at least two groups of mammaliaforms diversified there and survived until at least the end of the Cretaceous. This biogeographic dichotomy strongly suggests that the common ancestor of the crown group Mammalia will be found in the Middle or Early Jurassic, if not earlier.

Cretaceous–Tertiary Mass Extinction and its Consequences

Only the effects of the Permian–Triassic mass extinction overshadow the extent of devastation of marine and terrestrial biotas during the Cretaceous–Tertiary mass extinction. On land, the Cretaceous–Tertiary mass extinction is marked by the demise of nonavian dinosaurs and some other vertebrate lineages (Dingus and Rowe, 1998; Fastovsky and Weishampel, 2005). Similarly, many dominant groups of marine invertebrates and aquatic reptiles died out at this time.

The primary source of information documenting the effects of the Cretaceous–Tertiary mass extinction on mammalian evolution is a series of fossil localities in an area of the Western Interior of North America extending from Colorado northward into Alberta. For decades, a wide range of geological and paleontological research projects have been under way in this area, and the resulting database is extensive. This is both a curse and a blessing. There has been a tendency to regard the

results of studies of biotic change in the North American Western Interior as typical of global patterns. Recent discoveries show that this was not the case. However, although geographically limited, the extensively documented patterns of survival and extinction in the North American Western Interior can be used to test the hypotheses concerning the nature and severity of environmental changes that caused the Cretaceous–Tertiary mass extinction.

Wilson (2005), Archibald (2011), and others have analyzed the patterns of survival and extinction of terrestrial vertebrates based on extensive collections from northeastern Montana. During the Cretaceous–Tertiary mass extinction in this area, all the nonavian dinosaurs, approximately 20 genera, became extinct. A small group of freshwater sharks and their relatives shared the fate of the nonavian dinosaurs. These losses, plus extensive extinctions among the Cretaceous lineages of lizards and marsupials, account for almost 75% of the extinctions of the terrestrial vertebrate species in the North American Western Interior. In contrast, no extinctions of lineages of salamanders and frogs have been documented. Only a few species of turtles, crocodilians, and crocodilian-like reptiles died out at this time. Several paleontologists have begun to analyze the very fragmentary fossil record of the evolution of birds in the Late Cretaceous. Their research, including molecular studies of modern forms, shows that the evolutionary diversification of the crown group of birds had begun in the Cretaceous. Although many lineages of more primitive birds died out before or at the Cretaceous–Tertiary boundary, extinction appears to have taken little toll among the basal lineages of the crown group. Among the mammalian lineages present in the North American Western Interior, approximately 60% of the species of multituberculates, which are thought to be the ecological equivalents of rodents, became extinct during the Cretaceous–Tertiary mass extinction. Almost all lineages of eutherian mammals probably survived this event. In stark contrast, all but one or two of the Cretaceous lineages of marsupials appear to have become extinct at this time. The currently available fossil records from other continents in the Northern Hemisphere are characterized by the lack or very limited documentation of their latest Cretaceous and earliest Tertiary vertebrate faunas.

Recent discoveries in Australia and, particularly, South America are beginning to outline the course of mammalian evolution through the Cretaceous–Tertiary mass extinction in the Southern Hemisphere. At this time, Australia, Antarctica, and South America were closely approximated and global climates were much warmer. Direct evidence documents at least some interchange of mammals between Australia and South America. In South America, deposits laid down several million years prior to the end of the Cretaceous contain records of a mammalian fauna dominated by members of several lineages of mammaliaforms accompanied by a lineage of monotremes. A gap in the fossil record separates records of this fauna from deposits documenting the earliest Tertiary faunas known from the area. The change in mammalian faunal composition is striking. Most of the mammaliaform lineages had disappeared. A lineage of monotremes survived into the Tertiary but soon became extinct. The dominant mammals in the earliest Tertiary of South America included a small but diverse group of marsupials, which were

accompanied by a few lineages of placental mammals. These marsupials and placentals appear to be derived from stocks that dispersed southward from North America about the time of the Cretaceous–Tertiary boundary or earlier. A great gap separates the youngest Cretaceous records of mammaliaforms and the oldest Tertiary records of mammals in Africa.

The distal causal factors of the Cretaceous–Tertiary mass extinction are the subject of continuing debate. The pattern of survival and extinction of species of terrestrial vertebrates at the Cretaceous–Tertiary boundary and the role of immigration in their recovery in the earliest Tertiary in the North American Western Interior argues strongly against, if not falsifies, hypotheses calling for global catastrophically destructive changes in the environment as distal causal factors of this mass extinction. Massive volcanic deposits in peninsular India document a period of extensive flood basalt eruptions similar to those that occurred around the Permian–Triassic and Triassic–Jurassic boundaries. These eruptions began before and continued across the Cretaceous–Tertiary boundary. The end of the Cretaceous was a time of major marine regressions linked to changes in continental climates and opening routes of dispersal for terrestrial vertebrates. Discovery of a large crater in Yucatan adds evidence supporting the hypothesis that an asteroid, or other extraterrestrial body, impacted the earth at the close of the Cretaceous. The press–pulse model of extinction (Arens and West, 2008) suggests that extraordinary volcanic eruptions modifying the atmosphere, the consequences of marine regressions, and possibly other factors contributed to changes in global environments stressing Late Cretaceous marine and nonmarine biotas. As a consequence of these stresses, a relatively minor change in the environment might have triggered the mass extinction.

Recovery of Mammalian Faunas During the Early Paleocene

The discovery and collecting biases favoring the fossil record from the Northern Hemisphere continue to limit analyses of the course of mammalian evolution immediately after the Cretaceous–Tertiary extinctions, which marked the end of the second phase of synapsid evolution. Earliest Paleocene faunas are well known only in the North American Western Interior. In northeastern Montana and immediately adjacent areas, a refined fossil record provides the basis for study of the recovery of the mammalian fauna during the first million years of the Paleocene (approximately 65–64 Ma). Radiometric age determinations make it possible to subdivide this period of faunal recovery into a first interval of approximately 400,000 years and a second of approximately 600,000 years (Wilson, 2005).

In the first 400,000 years of the Paleocene, taxonomic diversity of the mammalian fauna of the North American Western Interior was depressed in comparison to that of the latest Cretaceous. The members of a few surviving lineages rapidly increased in abundance, for example, genera of the multituberculates. Only one or two lineages of marsupials survived but their representatives were not abundant. Abundant members of these early faunas were placentals, primarily represented by the paraphyletic condylarths, the so called archaic ungulates. This group is allied to lineages of modern

ungulates, hoofed mammals, which would make their appearance later in the Paleocene or in the Eocene. All these earliest Paleocene mammals were characterized by small body size. As far as can be determined from their fragmentary remains, none of them were larger than the largest, latest Cretaceous mammals known from the area, which were about the size of modern opossums or raccoons (Wilson, 2005).

Less than half of the mammalian species in this earliest Paleocene fauna represent lineages present in the preceding latest Cretaceous fauna of the northern Western Interior. The majority is composed of immigrants that appear to have differentiated in other areas and then dispersed into the Western Interior after the Cretaceous–Tertiary mass extinction. This is one line of evidence that suggests the diversification of major placental lineages had begun in other, as yet unsampled, areas prior to the end of the Cretaceous. Support for this view also comes from recent comparative molecular studies of modern placental mammals. Through application of molecular clock techniques, these studies have produced hypotheses suggesting very ancient times, the middle or early part of the Cretaceous, for differentiation of major placental lineages. This conclusion directly contradicts the currently available fossil record, which suggests that the early differentiation of these lineages occurred at most in the latest Cretaceous or was a product of the rapid evolutionary radiation of placentals in the Paleocene (Wible *et al.*, 2007). Probably the history of placental evolution is to be found somewhere between these extremes.

During the next approximately 600,000 years of the Early Paleocene mammalian, particularly placental, diversity in the Western Interior increased greatly. In part, this increase was the result of diversification of lineages present in the area at the beginning of the Paleocene, but immigration of additional groups of placentals and multituberculates from other areas played a significant role. During this interval, body size increased in several lineages. For the first time since the Late Triassic, a few placentals and multituberculates achieved body sizes larger than modern opossums or raccoons and approximating those of modern middle-sized mammals. These trends for increasing taxonomic diversity and appearance of species of larger body size continued throughout the later part of the Paleocene.

Mammalian Evolution During the Tertiary

From the Late Paleocene onward, mammalian faunas of the Northern Hemisphere are increasingly well documented by assemblages of fossils from both Eurasia and North America. Similarly, the available fossil records of Africa, peninsular India, South America, and Australia document the evolution of mammals and other terrestrial vertebrates, particularly later in the Tertiary. After the initial recovery of the mammalian fauna of the Northern Hemisphere from the effects of the Cretaceous–Tertiary mass extinction, taxonomic diversity continued to increase, and many lineages were characterized by the evolution of larger individual body size. Before the end of the Paleocene, some species had attained the bulk of modern rhinos or hippos.

The boundary between the Late Paleocene and Eocene was marked by both a brief period of significant global warming

(the Paleocene–Eocene Thermal Maximum) and significant faunal turnover. In the Northern Hemisphere this was the time of appearance of a number of placental lineages that are represented in modern faunas; for example, it was the time of appearance of the modern orders Perissodactyla (including horses), Artiodactyla (including pigs and deer), and Primates. Additional contributions to mammalian diversity came with the first records of flying mammals (bats) and the appearance of one group of marine mammals (whales). Also, there were instances of decreases in diversity or extinction of major lineages, for example, during the Late Paleocene and Eocene, the diversity of the multituberculates decreased with the appearance and diversification of rodents. In general, however, the taxonomic diversity of terrestrial mammals increased. The sparser fossil records from South America document a radiation of endemic lineages through the Eocene. About the end of the Eocene, immigrant rodents and primates made their appearance. The Eocene faunas of Africa were characterized by both diversification of endemic lineages, for example, the Proboscideans (elephants and their kin) and immigrants from Eurasia (Rose, 2006).

Near the Eocene–Oligocene boundary, approximately 33.7 Ma, many mammalian lineages became extinct. In comparison to other extinctions, this was not an abrupt mass extinction event but an interval of faunal turnover. It occurred during a time of a marked cooling in global climates. Losses were most frequent in groups of placentals thought to have been particularly adapted to widespread tropical forests of the Eocene. In addition to having been cooler, Oligocene climates were characterized by a general increase in aridity and decrease in equability reflected in the expansion of areas of savanna and steppe.

Mammalian diversity in the Northern Hemisphere, measured at the family level, reached a maximum in the Miocene (the Mid-Miocene Climatic Optimum), particularly reflecting a radiation of several lineages of ungulates and rodents. Through the remainder of the Tertiary, the diversity of large ungulates decreased as the climate became cooler and dryer. Although differing in detail, broadly similar patterns in the incidence of extinctions and faunal turnover characterize the evolutionary history of mammalian faunas of the continents of the Southern Hemisphere. Until recently, climatic changes were thought to be the major, if not the only, driving force in mammalian evolution during the later Tertiary. A variety of high-resolution paleontological and geological methods were used to describe and test these hypothesized correlations. The results indicated that times of climatic change and periods of increased diversification or extinction were not precisely correlated. Other environmental or biological factors apparently contributed to controlling the course of later Tertiary mammalian evolution.

Conclusions

The approximately 300-million-year history of synapsid evolution can be subdivided into three major phases. During the first phase, nonmammalian synapsids were among the dominant terrestrial vertebrates. The second phase, which began in the Late Triassic and lasted until the end of the Cretaceous, was characterized by the dominance of the dinosaurs in

terrestrial faunas. Mammaliaform synapsids and early mammals were a lesser component of these faunas. The third phase began after the Cretaceous–Tertiary mass extinction and was characterized by a major diversification of mammals returning them to a dominant position.

In addition to the ongoing effects of background extinction, mass extinctions played a significant role in directing the course of synapsid evolution. The Permian–Triassic and, particularly, the Cretaceous–Tertiary mass extinction events greatly reduced synapsid diversity and reset the course of its evolution. Other major turning points in the evolution of the group, which involved extensive extinctions of lineages, were not coincident with mass extinctions – for example, the periods of faunal turnover late in the Triassic or during the transition from the Eocene into the Oligocene.

Attempts to compare patterns and causal factors of pre-Quaternary and Quaternary mammalian extinctions must consider the significant differences in resolution of the timescales at which these events can be studied. In some instances, the fossil record of Quaternary, particularly later Quaternary, extinctions permits analysis of biological change on ecological timescales of hundreds or thousands of years. Resolution of the pre-Quaternary record is much less. The severity of these extinction events may be artificially compounded by our inability to distinguish events that occurred at different times over intervals of hundreds of thousands or a few million years.

Finally, a survey of current research on the distal causal factors of mass extinctions and periods of rapid faunal turnover in synapsid evolution indicates that there probably was not a single grim reaper. Varying combinations of the effects of modification of the configuration of oceans and their patterns of circulation, increases in the intensity of volcanic activity, and the sporadic impacts of extraterrestrial bodies all contributed to sometimes deleterious changes in the physical environment. Similarly, biotic factors played a part. The degree of interdependence of the members of an ecosystem, for example, contributes to the system's resistance to environmental change. At different times in the pre-Quaternary history of mammalian evolution, all these and probably other factors caused extinctions of lineages.

Glossary

Brachyodont Low-crowned cheek tooth commonly found in omnivorous or burrowing animals.

Cloaca The chamber into which the gut and urinary and reproductive tubes empty before exiting the body.

Diastema A large gap between incisors and premolars that is thought to permit an animal space to manipulate food with the tongue.

Fossorial A burrowing animal.

Macropod A marsupial in the family Macropodidae, the kangaroos and wallabies.

Marsupium Folds of skin that envelope the mammary glands and provide protection to infants: found in metatherian and protherian mammals.

Monophyletic Descriptive of a clade, or branch, of an evolutionary tree that has a single root, indicating that all members of that branch are descended from a common ancestor.

Phylogeography The study of the relationship between and among genetics, morphology, paleontology, and ecology to better understand the spatial aspects of evolution.

Polyphyletic Descriptive of a group of animals that, although grouped together in a phylogeny or evolutionary tree, do not share a common ancestor.

Semelparous Species that breed once and die.

Ranging in size from a shrew, which may weigh only a few grams, to the blue whale, which weighs more than 150 metric tons, mammals are found in the air, on the ground, under the earth, and in the oceans, rivers, and lakes of the world. Modern mammals are represented by 151 families divided into 1226 genera, not an impressively diverse group of animals. Throughout geological history, there have been just more than 400 families of mammals and perhaps as few as 5000 genera. Paleontologically, the structure of the mammalian middle ear is unique, with three small bones that were originally found in the jaw of more primitive vertebrates now forming the structure of the middle ear. Mammals are endothermic; that is, they regulate their internal temperature. To support endothermy, mammals have greater cellular production of energy, lungs with a large capacity, and numerous red blood cells to transport oxygen; an efficient four-chambered heart; and increased digestive efficiency. Soft-tissue characters that are diagnostic of mammals include sweat glands, hair, a folded cerebellum, an epiglottis, and a complex lung structure. Of course, mammary glands are the single most common diagnostic feature for mammals: the production of milk with which to feed and nurture young is a shared feature of all mammals.

Introduction to Mammals

Modern mammals are not an impressively diverse group of animals, at least not numerically. Mammals are an extremely well-described class of animals, with, perhaps, only *Aves* being better examined. Well described and relatively well studied, modern mammalian diversity is limited to 29 orders, divided into 151 families with 1226 genera and classified, at present, into approximately 4800 species (Figure 1). Mammals have about half the diversity of modern birds and pale in significance when compared to the more than 1 million described species of insects and the perhaps 10 million species that

remain undescribed. Historical consideration does little to mediate these discrepancies in diversity: throughout all geological history, there have been just more than 400 families of mammals and perhaps 5000 genera.

What mammals lack in numeric diversity is made up in their physical and ecological variation. Ranging in size from just a few grams (e.g., shrews in the family Soricidae) to more than 150 metric tons (the blue whale, *Balaenoptera musculus*), mammals are found in the air, on the ground, under the earth, and in the oceans, rivers, and lakes of the world. Their diversity of body types, diets, and habits has captivated both the general public and scientists, taking an entirely disproportionate share of scientific study and popular examination.

What is a Mammal?

There are literally dozens of diagnostic characteristics of mammals, most of which are related to soft-tissue structure and metabolic function. For paleontological purposes, soft-tissue differentiation of mammals is of little or no value. Soft tissue is rarely preserved and its structure can only occasionally be deduced from the structure of the bones that it covers and from which it is suspended. Paleontologists, therefore, look for skeletal and cranial features that distinguish mammals from other classes. One defining character is found in the structure of the mammalian middle ear. The middle ear contains three small bones, the stapes, incus, and malleus, which were originally found in the jaw in the craniomandibular joint of more primitive vertebrates (the joint where the jaw meets the cranium). The simplification of the craniomandibular is also reflected in further simplification and solidification of cranial bones overall. This simplification and increased ossification are also reflected in the postcranial skeletal structure of mammals. Skeletal growth occurs early in the life history of mammals, with further growth of bones limited to a cartilaginous area at the end of the bone, under the articular

Figure 1 Species diversity of recent mammalian orders. Data derived from Vaughan TA, Ryan JM, and Czaplewski NJ (2000) *Mammalogy*, 4th edn. Philadelphia: Saunders College Publishing. All taxonomy is based on Wilson and Reeder (2005).

surface, called the epiphysis. Eventual closure and ossification of the epiphyses occur after growth is complete.

Physiologically, a critical difference between mammals and reptiles is the development of endothermy, or internal regulation of temperature. While it is unclear whether the mammal-like Therapsids were endothermic, all modern mammals exhibit endothermy, whereas extant reptiles are ectothermic, using behavioral adaptations to regulate temperature in harsh environments or allowing their temperature to fluctuate widely. The cellular and structural differences that endothermy require are all hallmarks of mammalian life: greater cellular production of energy, lungs with a large capacity, and numerous red blood cells to transport oxygen, efficient circulatory systems, and increased digestive efficiency. Soft-tissue characters that are diagnostic of mammals (many of which are related to endothermy) include sweat glands, hair, a four-chambered heart, a folded cerebellum, an epiglottis, and a complex lung structure. Of course, mammary glands are the single most common diagnostic feature for mammals: the production of milk with which to feed and nurture young is a shared feature of all mammals.

Overview of the Class Mammalia

Mammals are usually divided into three subclasses: the Allotheria, which was represented by the extinct multituberculates; the Prototheria, which reached the peak of its diversity in the Mesozoic and which today is represented by a single order, Monotremata, containing the four species of echidna (*Tachyglossidae*) and the duck-billed platypus (*Orithorhynchus anatinus*); and the Theria, which contains two infraclasses the Metatheria (marsupials) and the Eutheria

(placental mammals). Debate continues about the unique origin of the Prototheria.

Monotremata

Viviparity, or live birth of young, is so common among mammals that it is usually, wrongly, considered a defining character of the class. The five species of the order Monotremata all lay eggs. The platypus lays its eggs into a nest, similar to a bird's nest, whereas all four species of the family *Tachyglossidae*, the echidna, or spiny anteaters, lay their eggs directly into a marsupial-like pouch. Although this curiosity is the root of the common name for the monotremes – egg-laying mammals – the egg is actually a rather insignificant aspect of the monotreme's life history. Incubation is brief, under 2 weeks, following which monotreme development does not differ significantly from that of other mammals. Clearly mammals, they nurture their young with milk that is expressed from mammary glands that lack nipples. Like all mammals, they are endothermic, have hair, possess a single jaw bone, and have the diagnostic three-bone middle ear structure.

Divergence of the monotremes from other mammals occurred approximately 175 million years ago early in mammalian history. Fossil monotremes have only been found from Australasia, and all extant species share this distribution. Monotremes appear to be extremely primitive in their reproductive habits, with not only an egg-laying habit but also a single opening, or cloaca, into which both the excretory and reproductive tracts exit. The cloaca (or single exit) gives the order its name.

Theria

The therian mammals all share the derived character of live birth of their young. The subclass Theria is divided into

two infraclasses: metatherians and eutherians. Metatherians are usually called marsupials because of the pouch, or 'marsupium,' that many members of the subclass possess. A far more diverse order than Monotremata, there are 331 described species of marsupials, which are categorized into 21 families. Metatherians and eutherian mammals probably diverged at about the same time as the monotremes, approximately 100 million years b.p. Since that time, the two major groups have had a divergent, and sometimes convergent, evolutionary history.

Metatheria: Marsupials

In recent times, metatherian mammals have only been found in the Australian subcontinent, the adjacent large islands of New Guinea (the island consisting of Papua New Guinea and the Indonesian province of West Papua) and Tasmania, and the Neotropics. This distribution is more restricted than that given by fossil evidence. Arising in the Mesozoic, about 100 million years ago, marsupials are first found in North and South America. The metatherians made their first appearance in the fossil beds of the Eocene of Europe, 50 million years ago, and it is thought they arrived in Asia, and Australasia, some time thereafter. The fossil evidence for this period from these regions is poor, and some have suggested that this, combined with the present distribution of marsupials, strongly implies an Antarctic origin.

In the New World, the recent marsupial fauna has not developed significant diversity in competition with placentals. The New World family Didelphidae is represented by 87 recent species in 17 genera. Although found across North, Central, and South America, there is relatively little variation in size, with the smallest member of the family the size of a mouse and the largest only the size of a large cat. The most common species in the Americas is the Virginia, or common, opossum (*Didelphis virginiana*), which is widespread and extremely successful in adapting to human presence. The earliest members of this genus are found in South America and it appears that they migrated to North America just more than a million years ago after the establishment of the Central American land bridge. Although marsupials, for the most part, did poorly when they invaded North America, *Didelphis* is a clear exception to this rule.

In South America during the late Miocene and Pliocene epochs (approximately 5–10 million years b.p.), a diverse radiation of marsupials occurred. Convergent evolution produced a suite of marsupials that resembled contemporaneous placental mammals and included forms similar to large felids (in the family Thylacoleonidae). The most diverse family of carnivorous, South American marsupials was the Borhyaenidae, often called the family of dog-like marsupials because of the general resemblance of some species to canids (e.g., *Lycopsis*). Borhyaenids persisted only until the late Pliocene. Other families of South American fossil marsupials included rodent-like, mole-like, and rhino-like animals and perhaps the best known, the Thylacosmilidae, or the 'false' saber-tooth tigers (*Thylacosmilus*).

In the Australian region, until recent times, the metatherians have been free from competition with placental mammals, with the exception of bats and some muroid rodents (rats and mice). Here, the metatheria have undergone a

remarkable and fascinating radiation. Many species resemble, in basic form, the eutherian moles, squirrels, and small carnivores. These species tend to be relatively undifferentiated and follow a relatively similar body form within groups. In some cases, however, marsupials in Australia have evolved into forms that little resemble in structure their ecological replacements in areas where placental mammals dominate. Whereas most grazing placental mammals are, to a greater or lesser extent, relatively similar in their body plan, the kangaroos and wallabies (Macropodidae) represent a distinctly different solution to the design of a grazer. The origin of the large ricochetal hind feet and vestigial, but highly flexible, forearms suggests an arboreal origin for the family.

Eutheria: Placental mammals

The greatest diversity of mammals is seen in the eutherians. Both through geological time and in the present, eutherians are the most diverse of the three main branches of mammalian evolution. Representing nearly 95% of the extant species of mammals, eutherians have shown a remarkable variety of forms and adaptations. Fully aquatic forms are represented by the 11 families and 84 species of cetaceans. The 18 families of Chiroptera, representing more than 1000 species, have a near monopoly on the nocturnal skies and are keystone pollinators in tropical forests. But by far the most diverse order is Rodentia, with 33 mammalian families (approximately 22% of the total) and more than 2200 species, nearly half the known mammals alive today. A more thorough discussion of eutherian diversity is given below (*see* Placentals for a description of each Order).

One would expect that the defining character for eutherian mammals is the well-developed placenta, from which the infraclass derives its name. The use of the term is unfortunate as marsupials possess one of four types of more primitive, but nonetheless well-developed, placenta, and placenta-like structures are seen in some fish and reptiles. In all mammals, the placenta serves to provide exchange of nutrients and waste products and acts as a respiratory organ for the developing fetus. Increased complexity of the placenta found in eutherian mammals allows for more efficient transfer and for added functions, including endocrine production, including progesterone, which helps sustain pregnancy.

Differentiating Between Placental and Marsupial Mammals

Cranial and Skeletal Differences

Differentiation of marsupial and placental mammals is easiest in the examination of soft tissues; nonetheless, there are a set of diagnostic characters that distinguish the metatherian and eutherian mammals. Whereas the palates of placental mammals are smooth, those of marsupials have a series of diagnostic holes or vacuities. Marsupials also differ in their dental morphology: in contrast to the serial replacement of deciduous teeth with permanent teeth found in placentals, only a single tooth is replaced in each jaw. With the exception of the third premolar, all premolar, canine, and incisor deciduous teeth are resorbed before they erupt in the jaw. Only a single set of molars forms, erupting sequentially. Recent fossil evidence from the Mesozoic marsupial *Alphadon* shows that this pattern

of tooth replacement and development is a derived character and suggests that the trait is ancestral to marsupials.

A further primitive character common to the Monotremata and Metatheria, but thought to be lost in the eutherian mammals, is the epipubic bones, which extend forward from the pubic bone in both sexes. Hypotheses about the function of the epipubic bones have been various. Initial speculation was that the structure provided support for the attached young found in marsupials or support for the marsupium, in which they are often contained. Others have suggested it was involved with locomotion, although more recently it has been proposed that epipubic bones provided a place for the attachment of abdominal muscles, thus allowing for greater expansion of the abdominal cavity, increasing the function of the diaphragm and improving efficiency of respiration. Recent paleontological finds show that epipubic bones were present in Cretaceous eutherian mammals. Because the loss of epipubic bones is associated with prolonged gestation, these findings have been interpreted as evidence that the complex suite of adaptations that typify placental mammals were derived later in the evolution of eutherians.

Reproduction

Whereas placental mammals tend to have long gestation periods and relatively short periods of lactation, gestation in the marsupials is always relatively brief and is followed by a much longer period of lactation. Typically, neonatal marsupials are extremely small, only a few grams, and show very incomplete development. The exception to this generality is seen in the jaw and forearm structure of the neonate: the nearly embryonic young need strong arms to navigate up the mother's midline to the teat and well-developed jaws with which to form an immovable attachment to the teat once arriving. A greater proportion of development occurs outside the mother's uterus after the neonate has attached to a teat. In approximately half the marsupial species, the teats are found inside a marsupium. By the time the neonate leaves the pouch, or detaches from the teat, it weighs more or less the same as a placental mammal of an equivalent adult size.

Diagnostic differences in the structure of the reproductive tract of female marsupials and in the development of the embryo may explain many of the life history differences between eutherian and metatherian mammals. While eutherian mammals form a complex placenta that nourishes the embryo, marsupials retain an eggshell membrane with a simple yolk sac to nourish the young. This arrangement limits the nutrients that a mother can transfer to her embryos.

The size of a neonatal marsupial is also limited by the structure of the female reproductive tract. In eutherian mammals, the reproductive tract is arranged linearly (Figure 2): the vagina leads directly into the uterus, with two ureters transporting urine from the bladder to the urethra. Growth of the fetus is essentially constrained only by the size and elasticity of the vaginal canal. Given that the spotted hyena gives birth through a vagina that has evolved to look like a pseudopenis, this constraint does not appear to be too great. In contrast, in marsupials, the structure of the vagina and uterus is like a double jug handle (Figure 2). Just above the urethra, two lateral vaginas form loops on either side of a

Figure 2 Comparison of eutherian and metatherian reproductive tracts. Reprinted from Sharman GB (1970) Reproductive physiology of marsupials. *Science* 167: 1221–1228, with permission from American Association for the Advancement of Science.

pseudovaginal canal. The two vaginal loops rejoin and feed into a bipartite uterus. The ureters pass inside these vaginal loops. Because birth takes place through the lateral vagina, placement of the ureter inside this loop may limit the size of the neonate.

Mammalian Phylogeny

Early History

Mammals have their origins deep in geological history. Just more than 200 million years ago, in the late Triassic period, primitive cynodont mammals evolved from their mammal-like reptile progenitors, the Therapsids. The Therapsids, whose members dominated the terrestrial landscape during the Triassic, faded into insignificance by the end of the Triassic/Jurassic boundary, leaving the stage of the late Mesozoic era open to the radiation of great sauropods, the dinosaurs. For 140 million years, dinosaurs filled most terrestrial (and many aerial) ecological roles, with mammals for the most part relegated to small, terrestrial rodent-like forms.

The earliest evidence of true mammals occurs in the late Triassic, although by this time, mammals were found worldwide, suggesting a somewhat earlier divergence from the mammal-like cynodonts. Poor fossil records from many areas leave gaps, which slowly are being filled. Although the Mesozoic mammals were once thought to be lacking diversity, recent finds suggest this was not the case. Fossil evidence suggests they were never abundant and rarely showed any great size – the first mammal weighing more than 1 kg does not appear in the fossil record until the early Cretaceous. Yet a variety of unusual forms evolved in the Mesozoic, including Symetrodonta, which are characterized by well-developed, triangular molars, the predatory Triconadonta, and the omnivorous and herbivorous members of the Multituberculata.

The great radiation of modern mammals began in the mid-Cenozoic era, in the late Cretaceous period, approximately 100 million years ago. More rapid evolution of larger body sized mammals did not begin until the mid-Cenozoic, beginning about 65 million years ago during the Paleocene epoch of the Tertiary. Following this, mammalian radiation accelerated.

Ordinal Diversification

Structure of the Mammalian Evolutionary Tree

The ordinal diversification of the mammals was more or less completed in the late Eocene, 50 million years ago, and has been relatively stable since that time. Of the 32 major orders that were present 50 million years ago, 20 are extant. Reconstruction of evolutionary paths of ordinal diversification can be made using morphological analysis of modern or fossil taxa, molecular analysis (limited to species from which deoxyribonucleic acid (DNA) can be extracted), or some combination thereof. Extant species have often lost defining skeletal and cranial characters present in earlier fossil forms but have the advantage of soft tissue being available for study. Fossils offer a long time frame, but significant gaps in the fossil record and the absence of soft tissue for comparison may be problematic. Molecular genetic studies have become increasingly sophisticated but suffer from their own inaccuracies and, of course, are relatively useless for independently reconstructing phylogenies from taxa that have gone extinct, leaving no modern (or DNA-bearing fossil or subfossil) forms.

Molecular data have revolutionized our understanding of the phylogenetic structure of the major mammalian orders and have brought us closer to resolving significant questions about the exact relationship of several orders. Recent studies group mammals into four different clades: Afrotheria (which includes golden moles, tenrecs, elephants, and dugongs), Xenarthra (which includes armadillos and anteaters), Laurasiatheria (which includes whales, cows, shrews, bats, and dogs), and Eurarchontoglires (which includes rodents, primates, and flying lemurs). These new connections are surprising, given that, with the exception of the Xenarthra clade, the animals within these groups have extremely different morphology. Up until recently, the phylogenies of this 'supertree' was much less clear, with the availability of data being the most limiting factor. However, studies performed in the past decade have been able to analyze more diverse molecular datasets with a higher number of species. A theory currently exists that plate tectonics played an important role in the early evolutionary history of placental mammals, based on the numerous occurrences of convergent evolution found in the new tree's results.

A good example of a problem potentially solved by molecular analysis is the placement of the Hyracoidea, the hyraxes. Both protein sequence data and morphological studies suggest a close affiliation of the hyraxes with the Proboscidea (elephants) and the Sirenia (dugongs and manatees). Yet other morphological analysis suggests that hyraxes and perissodactyls (rhinos, tapirs, and equids) share a common lineage. Gene sequence data, although not without problems of its own, has now comfortably placed hyraxes with the elephants and dugongs in the superordinal clade Afrotheria, separate from the perissodactyls (which are now in the clade Laurasiatheria).

Timing of Ordinal Diversification

While scientists agree that there was a period of rapid diversification of higher orders of mammals, the exact timing of this event is still hotly debated. At the root of this debate are the differences in timing derived from molecular and fossil

evidence. The data supporting the timing of events presented above, with the major ordinal diversification completed in the early Tertiary, are derived from the near lack of any fossil evidence for the existence of modern orders of mammals before the Cretaceous/Tertiary boundary 65 million years ago.

Advances in molecular biology have permitted more sophisticated molecular analyses of ordinal diversification of both birds (which are purported to have a similar timing of ordinal diversification) and mammals. These analyses, which employ a number of different genetic 'molecular clocks,' all point to an early ordinal diversification of birds and mammals sometime in the middle to late Cretaceous, approximately 90–100 million years b.p. That the estimated timing of diversification is similar for birds and mammals supports this interpretation. However, of greater interest is the coincidence of the timing of ordinal divergence and the fragmentation of emergent land areas at about the same time.

By the early Cretaceous, the two main land masses formed by the breakup of Pangea, Gondwanaland, and Laurasia had further subdivided into seven continents. By the late Cretaceous, 70 million years ago, 11 continents had appeared, the peak of land mass isolation and diversity. Earlier explanations had suggested that the rapid ordinal diversity resulted as mammals (and birds) radiated into a diversity of empty niches on the new continents. The molecular data suggest, however, that the breakup of land masses itself provided the opportunity for diversification.

If the molecular data are correct, fossil evidence for two dozen orders is 'missing' for upward of 30 million years, and by some estimates 60 million years, of stratigraphic history. The real question asked by many paleontologists, therefore, is, "How likely is it that an increasingly good fossil record could be devoid of evidence for such diversification?" The answer appears to be, not likely. Using standard models to examine the probability of not finding a species in the fossil record, scientists estimate that, even under the most severe conditions, there is a 2% chance of not finding earlier fossils if, indeed, ordinal diversification occurred before the Cretaceous/Tertiary boundary. One possible reconciliation of these two viewpoints would be the Cretaceous splitting of a few lineages, thus giving rise to earlier ordinal diversification, followed by a rapid radiation during the Paleocene.

Whatever the timing of the ordinal diversification of mammals, by the mid-Tertiary, continental drift resulted in a relatively large number of isolated land masses, evolutionary caldrons in which mammalian diversification occurred. Peak continental isolation occurred at the Cretaceous/Tertiary boundary when landmasses, which in modern times are joined, were isolated. This included present-day continents (e.g., South America and Africa) and subcontinents (e.g., India). Even landmasses that were joined, such as Asia and Europe, exhibited greater isolation as a result of landscape features. Diversification accelerated about 10 million years after this isolation was established, but recent work on the 'supertree' structure of mammalian radiations suggests a more complex history.

Island continents, in and of themselves, would have likely produced greater mammalian diversity over time. However, in addition to the isolation of continents, the Tertiary was a time of greater differentiation and seasonality of climates. Much

evidence exists for this, from diversification of Tertiary flora (particularly in the late Tertiary) to developments such as the Antarctic ice cap, which formed in the Miocene. Continental drift, with landmasses moving toward the poles, combined with concomitant changes in ocean currents resulted in increasingly temperate environments. For the homeothermic mammals, this diversification of ecosystems provided a unique opportunity for radiation. In recent times, geologically isolated continents and large islands, such as Madagascar and Australia, continue to show unique assemblages of mammals that are typified by high levels of endemism and diversification of a small number of families.

Phylogeny and Biodiversity: Patterns of Ordinal Diversification

Mammalian generic diversity appears to be rising exponentially throughout the most recent geological period, the Cenozoic. Whereas there is some fluctuation in the levels of diversity, the progressive increase in diversity is notable. This pattern may be driven, in part, by an increasingly heterogeneous environment. However, for the most part, the exponential rise is probably an artifact of an increasingly well-represented fossil record. Mammal diversity probably peaked during the mid-Tertiary, although patterns of diversification (and simplification through extinction) vary from continent to continent. The following sections will briefly describe patterns of diversity in the extant orders of mammals.

Monotremes

The five extant species of the Monotremata, found only in Australasia, all represent highly specialized representatives of an order that had an early branching from all other mammalian orders. Living monotremes are toothless, with the exception of young platypuses, a trait that has not made reconstruction of fossil history a simple task. Early fossil remains are known from Australia. A single fossil found in southern Argentina, dated to about 60 million years b.p., represents the only occurrence outside of Australasia.

Monotremes possess what are surely primitive mammalian characters such as egg laying and a cloacal reproductive/excretory structure. Although these primitive characters reflect an early divergence, monotremes are not primitive in all their characters. For instance, all five extant species of monotremes share complex and well-developed nervous systems. The most unusual sensory adaptation is the development of electroreceptors across the platypus' bill and in the tip of the echidnas, producing snout or beak. Unique among mammals, electroreception in monotremes is complemented by a complex and large brain.

Monotremes are also the only mammals that have the ability to deliver venom as a defensive measure. Although venom glands are vestigial in the echidnas, in the male platypus a well-developed venom gland is found in the hind legs. More active during the mating season, the venom is assumed to be a defense against intruding males. The venom is toxic to humans and lethal to small mammals.

The sole surviving representative of the family Ornithorhynchidae is the platypus, *O. anatinus*, found only in eastern Australia and Tasmania. The morphology of the species is so distinctive that after early examination of skins sent to London, they were pronounced a fraud. Weighing around a kilogram and with an overall length of 45 cm, the platypus has a broad, duck-shaped bill. The animal is covered in short, dense fur and has webbed feet with claws for digging. The animal is highly aquatic and solitary outside of the breeding season. Females will expand their burrows before breeding and, after mating, will 'gestate' one or two eggs for 10–12 days. After laying, the egg is incubated for a further 12 days. Lactation is protracted, approximately 4 months, but the young becomes independent soon after weaning.

The Tachyglossidae family is represented by two extant genera, Tachyglossus and Zaglossus. Zaglossus is endemic to the mountains of New Guinea and feeds primarily on earthworms and arthropods; it includes three species of long-beaked echidnas, or spiny anteaters: *Zaglossus bruijnii*, *Zaglossus attenboroughi*, and *Zaglossus bartoni*. Tachyglossus, with *Tachyglossus aculeatus* (short-beaked echidna) as its only species, has a distribution across much of Australasia, found wherever its primary prey, ants and termites, are abundant. Introduction of the dingo 10,000 years ago probably has reduced the range of Tachyglossus, much as it has been thought to have a similar effect on the platypus. The echidnas are larger than the platypus, with Zaglossus weighing up to 10 kg and Tachyglossus reaching about half that weight. The four species have thin protruding snouts and thick coats of dark brown fur interspersed with sharp quill-like spines. Patterns of reproduction differ from those of the platypus. The egg is deposited into a pouchlike structure, where it hatches 10 days later. The young stays within the pouch for 2 months and then nurses outside the pouch for a further 3 months.

Marsupials

Extant marsupials are grouped into seven orders, with 21 families, 92 genera, and 331 species (Table 1). In a pattern commonly seen among mammals, some lineages contain disproportionately more families, genera, and species than others. For instance, almost half of all extant marsupial families are in the order Diprodontia, whereas four orders are represented by only a single family. The distributions of genera within families, and species within genera, are also highly skewed. Three orders of marsupials are found only in the New World, whereas the remaining four orders are found in Australasia. The Old World continents of Africa, Asia, and Europe have no extant marsupial representation.

Didelimorphia

The American possums, or didelphid marsupials, represented by a single modern family, are found throughout South America, with the Virginia opossum (*D. virginiana*) found widely over eastern, central, and southern North America. A generalist capable of living on garbage, the Virginia opossum has shown a remarkable range expansion in the past two centuries, expanding its range from the southeastern US north into the central states and the southernmost fringes of eastern

Table 1 Diversity of recent Marsupials

Order	Common name(s)	Number of families	Number of genera	Number of species
Didelimorphia	American opossum	1	15	63
Paucituberculata	Rat opossum	1	3	6
Microbiotheria	Minito del monte	1	1	1
Dasyuromorphia	Thylacine, numbat, quoll, antechinus, Tasmanian devil	3	17	63
Peramelemorphia	Bandicoots	2	8	21
Notoryctemorphia	Marsupial mole	1	1	2
Diprodontia	Koala, kangaroo, wombat, wallaby, glider, feathertail, cuscus, phalanger	10	35	117
Totals		21	83	276

Canada and along the west coast up to and just over the Canadian border. In the past 50 years alone, the species has extended its range over an area of two million square kilometers. This expansion has been facilitated by the opossum's extreme potential fecundity. A female may give birth to up to 60 very altricial young, up to a quarter of which may successfully attach to one of her 15 teats.

Despite ranging in size from a small mouse to a large cat (25 g to 5 kg), most didelphids show a clear set of similarities. Arboreal habits are common in the Didelphidae as is reflected in the general morphology of family members. Hands and feet are well developed, with an opposable big toe on a hind foot that has five toes. Many species also have prehensile tails.

The dentition of most didelphids is relatively unspecialized, with 50 teeth found in most species. The family is dominated by generalists, many of which have wide geographic ranges. However, some of the more remarkable specialists are also found in the didelphids. The yapok, or water opossum (*Chironectes minimus*), is the only truly aquatic species, with a fully webbed hind foot and a carnivorous diet consisting of a variety of crustaceans, fish, and amphibians.

Paucituberculata

Paucituberculata is also represented by a single Recent family, the Caenolestidae. All six extant species, placed in three genera of shrewlike marsupials, are found only at higher altitudes in the Andean cordillera, from Ecuador south to Chile. Capable of killing small vertebrates with their sharp teeth, the caenolestids usually subsist on invertebrates, particularly earthworms. Weighing under 20 g, the shrew opossums are nocturnal omnivores, using their long snouts and tactile whiskers, or vibrissae, to locate and kill prey. The extant paucituberculates are represented by a much more diverse fossil fauna. In the Miocene, seven genera of caenolestids were represented by a large number of species with widespread geographic distribution and a relatively large diversity of life forms, including specialized predators.

Microbiotheria

A single recent species of Microbiotheria represents an order whose fossils have been found on three continents: South America, Australia, and Antarctica. With origins in the Paleocene, the microbiotherids are thought to have invaded South America while it was connected to Antarctica and

Australia via a southern land bridge. The historical diversity of the group in South America is poorly known. The extant arboreal marsupial mouse inhabits the forests of southern Chile and is nocturnal.

Dasyuromorphia

Dasyuromorphia is known from fossil evidence in Australia in the mid-Miocene (Dasyuridae), but by this time the order already exhibited a relatively large diversity of morphotypes. Extant members of the order are represented by three families and 71 species, more than 20% of all recent marsupials. All but two of these species can be found in the family Dasyuridae.

In historical times, the Thylacinidae were represented by a single species, the thylacine, or *Thylacinus cynocephalus*, also called the Tasmanian wolf or Tasmanian tiger. This species has been considered extinct since the last specimen died in captivity in 1936. Thought to have had a wide distribution across Australia, introduction of the feral domestic dog, or dingo, by Polynesians approximately 10,000 years ago probably led to its extinction in Australia. The cause of extinction of the relictual population in Tasmania is debated, although it was most likely the result of a number of interacting factors common to human predator extinctions: habitat loss, disease, and declining prey supplanted by sheep farmers, who hunted the thylacine because their livestock was perceived to have been threatened by predation. Although it is most likely extinct, tracks and sightings continue to be reported, thus its place in the order remains (Wilson and Reeder, 2005).

The Myrmecobiidae consists of a single, monotypic genus, represented by the numbat, or banded anteater. Weighing approximately 400–500 g, the numbat resembles a small grayish-red squirrel, with a long bushy tail, a half dozen lateral white stripes circling its abdomen, and a prominent protruding snout. As its family name would suggest, however, the numbat is a termite specialist. Like other termite specialists (e.g., the bat-eared fox of Africa), the historical distribution of the species was dictated by the occurrence of its primary prey. Although termites are found across southern and central Australia, today the numbat persists in small fragments of Eucalyptus forest and woodlands (hardly core habitat), its last refuges from agriculture and predation by the introduced red fox (*Vulpes vulpes*).

The 69 species of the family Dasyuridae are often called the marsupial carnivores despite the fact that most members of

the family are insectivores. Their dentition, although similar to that of most marsupials, is similar to the dentition of many carnivores, characterized by bladelike incisors, large, sharp canines, and upper molars modified with large, sharp cusps. Found across Australia and New Guinea, dasyurids are usually small, with most species weighing under 50 g. The family occupies a wide diversity of terrestrial niches, with the smallest species convergent on shrews (family Soricidae) found in Asia, Europe, and North America.

Some of the dasyurids, particularly species in the genus *Antechinus*, have remarkable life histories. For instance, Stuart's marsupial mouse, *Antechinus stuartii*, has a semelparous life cycle more similar to that of many insects than to that of a mammal. The species is usually arboreal but forages terrestrially for invertebrate prey. Mating is highly seasonal, with males competing aggressively for mates. Females produce an enormous litter for their size (10–12 offspring). The young forage independently at 3 months and are sexually mature by 10 months. What is most remarkable is that after mating, the males die, whereas females rarely survive to breed in a second breeding season. Similar patterns of reproduction are seen in other *Antechinus* species.

The two largest species of dasyurids rightfully deserve the name marsupial carnivore. The tiger quoll, *Dasyurus maculatus*, may weigh up to 7 kg (males) whereas the largest extant species of Australian carnivore, the Tasmanian devil (*Sarcophilus harrisii*), can reach the size of a medium-sized dog, weighing up to 9 kg. Like the thylacine, the Tasmanian devil once had a widespread distribution across Australia but is now extinct on the continent. It persists in Tasmania, perhaps because it is primarily a scavenger, not a predator, and thus is more catholic in its dietary requirements and less of a perceived threat to farmers. Both quolls and Tasmanian devils are usually solitary; however, aggregations of up to 20 Tasmanian devils have been observed around carcasses.

Peramelemorphia

Found from the deserts of Australia to the rain forests of New Guinea, the 21 species of bandicoots and bilbies are placed in eight genera and three families, the Peramelidae, the Chaeropodidae, and the Thylacomyidae. The bandicoots, found in Peramelidae and Chaeropodidae, are insectivorous or omnivorous and for the most part are ecological counterparts of insectivores. Most species forage by digging insects out of the ground. They have small, sharp teeth, and ecological studies show that, despite feeding specialization for insects, they are omnivorous and opportunistic in their diet choice. Thylacomyidae includes two species, the greater and lesser bilby. Similar to bandicoots, bilbies can be distinguished by their longer ears and burrowing abilities that allow them to dig extensive tunnel systems. While the lesser is most likely extinct, the greater is now exclusively found in central Australia (Wilson and Reeder, 2005).

Bandicoots vary in size from the rodentlike mouse bandicoot (*Microperoryctes murina*) at 15–18 cm up to the giant bandicoot, *Peroryctes broadbenti*, at 45–50 cm and up to 5.5 kg. In recent times, the evolution of bandicoots has taken separate paths in Australia and New Guinea. Majority of the five species of echymiperas, or spiny bandicoots, are found on New Guinea, with a few populations on small islands in

Indonesia, and one with a relictual distribution in the rain forests of Cape York in northern Australia. Little is known about the fossil history of this family, as New Guinea is all but lacking in fossil record. On New Guinea, species occur at different altitudes, with the most species occurring in mid-altitude regions of 1000–1500 m above sea level.

Like perrisodactyls and artiodactyls, peramelid bandicoots show relatively extreme reduction in their limb morphology. Many peramelids have digitigrade elongated hind limbs, with expanded growth of the fourth digit, and lateral digits showing varying ranges of reduction. Reduction in limb digits suggests strong selection for running in the bandicoots. Whereas the bandicoots are remarkably cursorial, some of the elaboration of the hind limb may also have evolved for improved digging and burrowing.

Notoryctemorphia

The only Australian marsupials adapted for a fossorial existence are the two species of the order Notoryctemorphia, *Notoryctes caurinus* and *Notoryctes typhlops* (northern and southern marsupial mole, respectively). The marsupial mole has a pale, golden yellow coat and a long, tubular aspect about 15 cm long, weighing 35–40 g on average. They have rudimentary, almost vestigial eyes, compressed neck vertebrae, and stubby, almost vestigial forelimbs with two well-developed claws on the third and fourth digits. Other digits have essentially disappeared. The hind limbs are flattened, with only three small claws, and are used to expel dirt from a burrow. Little is known about the behavior or ecology of these species, although they are believed to be solitary and have been observed to eat burrowing insects and their larvae.

Diprodontia

This order includes both the largest and smallest marsupials. The smallest member of the family Burramyidae, or pygmy possums, weighs 6–8 g (*Cercartetus lepidus*). Known only from fossil remains until 1996, the family is now known to have five extant species placed in two genera. At the other extreme of the diprodont scale are the members of the family Macropodidae, the kangaroos and wallabies. Whereas the smallest macropod, the rock wallaby (*Petrogale burbidgei*), weighs 1 kg, the great gray kangaroo may reach 90 kg and stand flat-footed at just more than 2 m. Diprodontia also shows the greatest morphological variation on any extant marsupial order. While it is beyond the scope of this article to review all 143 species in the 11 families that make up the diprodonts, a review of some of the more divergent taxa is informative.

The single species in the family Phascolarctidae, the koala (*Phascolarctos cinereus*), like the kangaroo, is emblematic of the Australian continent. Highly selective in its diet, the koala subsists entirely on the leaves of a few species of smooth-barked eucalyptus trees. Unlike many marsupials, the koala is slow to reproduce, with a single young born to a female each year and the time of dependency between mother and young stretching to up to 1 year. Sexual maturity is not reached until age three or four.

The feathertail glider (*Acrobates pygmaeus*) and the feathertail possum (*Distoechurus pennatus*) are the only two species in the aptly named family Acrobatidae. Found only in New

Guinea and with no known fossil record, both species have long stiff hairs on either side of their tails, from which they derive their name. The gliders, which weigh a mere 10–15 g, have membranes between the elbows and knees, further aiding gliding flight. The membrane is lacking in the possum, which weighs up to 50 g.

Gliding as a strategy appears to have evolved twice in the diprodonts. Six species of lesser glider, three species of triok, and the striped and Leadbetter's possum make up the family Petauridae. Found from Tasmania to New Guinea, the petaurids resemble small squirrels. Weighing from 100 to 700 g, they have long bushy tails and stripes down their backs. The striped possum has black and white dorsoventral stripes along the back, resembling a North American skunk in coloration.

The six gliders bear a remarkable resemblance to flying squirrels of the genus *Glaucomys* in the Rodentia order. A membrane that stretches between their wrists and ankles provides an almost rectangular, kitelike gliding surface that these animals use to move from tree to tree. Whereas the striped possum is an insectivore, all other members of the family specialize on eating plant exudate (sap and gum) as well as insects. The sugar glider (*Petaurus breviceps*) is particularly specialized, concentrating its efforts on the exudate from a single species of *Eucalyptus*.

Resembling fossorial rodents, the three extant species of wombat have short, muscular limbs, stocky bodies, and broad long claws. They are large animals, weighing up to 40 kg. Prodigious diggers, they live in complex burrow systems, which caused them to be called marsupial badgers on their first discovery. Unique among marsupials, their teeth are ever-growing like those of rodents and lagomorphs. Wombats are herbivores, concentrating their diet on tussock grasses. Wombats are found only in southern Australia and Tasmania, with the northern hairy-nosed wombat (*Lasiorhinus krefftii*) found in one isolated population of 70 individuals living on 3 km² in central Queensland. Wombats have a long fossil history in Australia, with two much larger species occurring throughout the Pleistocene and going extinct about 10,000 years ago, coincident with the arrival of humans and dogs.

The best known family of diprodonts, and probably the most widely recognized family of marsupials, are the 11 genera and 65 recent species of macropods, the kangaroos and wallabies. Ranging in size from 1 to 90 kg, all species share the same basic body plan. Forelimbs are reduced and have five toes, all bearing small claws. The hind limbs are elongated, and, as in the bandicoots, on the hind leg all but the fourth digit has been reduced or lost. The large hind foot allows macropods to take a bipedal stance.

The limbs are highly adapted for ricochet or hopping locomotion that, because of the limb structure, is highly energy efficient. Each time the kangaroo bounces down, the large elastic tendons in the foot are stretched taut like a rubber band, storing energy from the previous bounce. As the foot is released, the tendons snap back and push the foot off the ground, throwing the kangaroo into the air. On landing, the tendons are stretched taut again, completing the cycle.

In addition to the remarkable limb adaptations, macropods have a digestive system remarkably similar to that of the eutherian ruminant herbivores they ecologically replace. Both groups have evolved segmented stomachs, with a true

chambered stomach in the ruminants and a divided, three-part stomach in macropods. This segmentation allows for the acquisition of foregut fermentation, in which symbiotic bacteria digest the tough outer cell walls of the plant materials that the animal eats, thus releasing nutrients from within the cell, providing a digestible form of cellulose (which is broken down by the bacteria), and nutrients from the bacteria themselves as they are absorbed when they pass through the gut.

Macropods have a wide geographic range and habits. Whereas macropods are usually thought of as long-distance, open-plains grazers, in New Guinea tree kangaroos in the genus *Dendrolagus* have adopted an arboreal habit. Although these animals still spend much of their time on the ground foraging for fallen fruits, they are agile climbers and use their large hind feet to propel them from tree to tree. Many of the smaller wallabies are also habitat specialists, such as the 16 species of rock wallabies (*Petrogale* sp.).

Placentals

Placentals dominate both the fossil and recent history of the Mammalia. With three times number of orders of marsupials (21 vs 7), placentals have shown remarkable diversification at all lower levels. Recent species are grouped into 21 orders with 130 families, 1134 genera, and approximately 4480 species (Table 2). As in the marsupials, some lineages contain disproportionately more families, genera, and species than others. With a fossil record stretching back into the Cretaceous, eutherian mammals have a long evolutionary history derived from marsupials and monotremes. Found on all continents, the placentals show remarkable niche diversification, occupying a wide variety of terrestrial, aerial, and aquatic habitats and subsisting on diets ranging from the true omnivorous habits required to live on the varied detritus of human populations to a single group of grasses (pandas and bamboo) or termites.

Pilosa

The superorder Xenarthra, which includes orders Pilosa (anteaters and sloths) and Cingulata (armadillos), encompasses a group found in recent times only in the New World. Thought to have occurred in Europe, the fossil record is, at best, fragmentary. To appreciate the diversity of the Xenarthra, take a journey back into Miocene South America. The modern-day sloths of Pilosa have quite the ancestral past; giant sloths, commonly called ground sloths or sloth bears, were as huge as their name would indicate. Whereas Tertiary radiations included a variety of species exploiting numerous habitats and niches, the members of the extant families of Pilosa are relatively or highly specialized: all four species of anteaters (*Mymecophagidae* and *Cyclopedidae*) are obligate ant and termite eaters, using their long, sticky tongues to collect their food. The sloths (six species in two families) have acquired an odd but apparently effective strategy, shifting along tree branches upside down, their spines hanging in a catenary curve. Sloths are the only green mammals; however, their color is not intrinsic to their fur but is derived from algae and cyanobacteria that grow in grooves in their hair. Sloths come down to the ground only to defecate.

Table 2 Diversity of recent Eutherian mammals

Order	Common name(s)	Number of families	Number of genera	Number of species
Xenarthra	Sloths, armadillos, and anteaters	3	13	29
Insectivora	Tenrecs, moles, hedgehog, shrew, mole	7	66	429
Scandentia	Tree shrews	1	5	19
Dermoptera	Colugo	1	1	2
Chiroptera	Bats	18	178	928
Primates	Apes, gibbons, marmosets, lemurs, galagos, Old World and New World monkeys	13	60	236
Carnivora	Canids, felids, mongoose, hyena, seals, weasels, racoons, otters	11	129	271
Cetacea	Whales, dolphins, and porpoises	10	41	78
Sirenia	Sea cows, manatees, dugongs	2	2	5
Proboscidea	Elephants	1	2	2
Perissodactyla	Equids, tapir, rhino	3	6	17
Hyracoidea	Hyrax	1	3	6
Tubulidentata	Aardvark	1	1	1
Artiodactyla	Pigs, peccaries, hippos, deer, antelopes, bovids	10	81	220
Pholidota	Pangolins	1	1	7
Rodentia	Rodents	29	443	2024
Lagomorpha	Rabbits and pikas	2	13	81
Macroscelidea	Elephant shrew	1	4	15
		115	1049	4370

Cingulata

Recently split into its own order from the current superorder Xenarthra, Cingulata contains 21 species of armadillo in its only surviving family (Dasypodidae). Arguably most impressive in Miocene South America (much like its Pilosa counterpart), numerous families of armadillos, including the Glyptodontidae, occupied the landscape with lumbering creatures up to 3 m long. The giant armadillo (*Priodontes maximus*), although half that length, is the largest extant species of armadillo, weighing up to 59 kg. Armadillos are distinguished by their jointed armor and are still endemic to the Americas.

Afrosoricida

Modern insectivores show a wide range of adaptations and are found on every continent except Australia. Taxonomy of the insectivores has been problematic, not only because the order contains some of the most primitive eutherian mammals, as well those with highly derived characters, but also because the order was used as the equivalent of a taxonomic wastebasket in which problematic families were thrown. The six families and 66 genera now classified as insectivores form a monophyletic (single-root clade) with ancient origins in the late Cretaceous or Paleocene.

Afrosoricida, one of the three new orders that split the abandoned order Insectivora, includes golden moles and tenrecs. Tenrecs (family Tenrecidae) show a disjunct distribution, found on islands of the western Indian Ocean (Madagascar, Comoros) and central Africa, and have probably been linked to Africa for all of their evolution. The family, which includes 30 species, can best be described as diverse. Although only ranging in body size from a shrew to a small cat (maximum weight of a kilogram), tenrecs have undergone a

remarkable radiation on Madagascar, expanding into vacant niches usually occupied by animals as diverse as otters, shrews, hedgehogs, and moles. Many species are omnivorous. The family Chrysochloridae, the golden moles, is restricted to southern Africa. The 21 species in nine genera are all fossorial and closely resemble both true moles (family Talpidae from another of the split orders, Soricomorpha) and the marsupial mole (family Notoryctidae from the marsupial order Notoryctemorphia).

Soricomorpha

Grouping the shrews and moles into a separate order, Soricomorpha is the second of the three orders that take the place of Insectivora, and is by far the largest in terms of species (428). Two families, Solenodontidae and Nesophontidae, were found in modern times only in the Caribbean. All of the Nesophontidae (also called West Indian shrews) are extinct. The four remaining Solenodon species are found in Hispaniola and, tenuously, in Cuba. Expansion of agriculture and introduction of rats, mongoose, and companion animals (dogs and cats) have led to decline of these species. Solenodon are shrewlike, have a distinctive, highly flexible snout and large hind feet, but are distinguished by an unusually large body size, weighing up to a kilogram. Fossil solenodons are known from North America from Oligocene deposits, approximately 30 million years b.p.

True moles, found in the family Talpidae, are found throughout the Northern Hemisphere and have long evolutionary histories in both Europe and North America. The talpids are more diverse than the Chrysochlorids, with a range of morphotypes including the star-nosed mole (*Condylura cristata*), which has nearly two dozen small, fleshy fingers arranged in a starburst pattern on its nose. This represents the

most bizarre elaboration of a general phenomenon found in the true moles, which have thousands of receptors arranged in a structure called the Eimer's organ on the snout. Cortical development of the brain is linked with the Eimer's organ. The Eimer's organ assists moles in navigating and foraging in their tunnel networks.

The fourth family in Soricomorpha, the Soricidae family, contains the shrews, represented by 26 genera. A very successful mammalian family, shrews are found on every continent except Australia and Antarctica. Soricidae also boasts the world's smallest living terrestrial mammal, the Etruscan shrew (*Suncus etruscus*), which weighs 1.8 g on average.

Erinaceomorpha

The last of the new forms of Insectivora, the order Erinaceomorpha contains hedgehogs and gymnures. The eight species of gymnures are found primarily in the rain forests of Southeast Asia. Gymnures are also called moonrats, and with good reason – they resemble rats much more than they do their much closer relatives, the hedgehogs. The 16 species of hedgehog are all well known for their spines, which are simply stiff hairs hollowed and supported by keratin, and their ability to roll into a ball as a defense mechanism.

Scandentia

The five genera and 20 species of tree shrews (families Tupaiidae and Ptilocercidae) are the only extant members of the Scandentia. The group is dispersed across the rain forests of southern Asia and Southeast Asia and has a relatively long fossil history (first found in the Eocene of Asia). Resembling a small squirrel, weighing 45–50 g, tree shrews have an elongated snout and a long, bushy tail. Like true shrews, many species are known to consume insects; however, the few scientific studies that have been conducted on the family have found that fruit is often the dominant component of the diet. Parental care is unusual, with the female giving birth to a small number of young (one to three) and hiding them in a nest. In a pattern more common in antelopes, the female visits the young to nurse and then leaves them lying in. Maturation is rapid, with independence from the mother at about a month and full sexual maturity at 4 months. Tree shrews are enigmatic in their phylogenetic affiliations. They have variously been assigned to the primates, flying lemurs (Dermoptera), and rabbits (Lagomorpha), with both molecular and morphological analysis producing contradictory results.

Dermoptera

Gliding, as opposed to true flying, is a mode of locomotion that has evolved independently in a number of mammalian orders. The two living species of Dermoptera (family Cynocephalidae), also called colugos or flying lemurs, are a relictual group of gliders found today only in the forests of Southeast Asia. Not closely related to lemurs, the dermopterans first appear in the fossil record in the Eocene of Thailand. Throughout their evolutionary history, only two families of colugos have been described, one North American and the other Asian. Affiliations of the order are unclear, with some paleontologists placing them as relatively close relatives to bats: they are not related to lemurs despite their common name. The gliding membrane, or patagium, stretching over the

animal's entire body, connecting along both sides of the tail to the legs, from legs to arms and from the arms to the neck, makes the animal look like a kite. Despite their relatively large size, reaching a maximum size just under 2 kg, the colugos are spectacular gliders, moving more than 100 m from tree to tree in the forest to reach the trees on which they feed. The colugo diet is herbivorous but may include leaves, fruits, and flowers.

Chiroptera

Bats represent the second most diverse order of mammals with 18 families, 202 genera, and 1050 species. Two major suborders of bat have been distinguished, the Megachiroptera, also called fruit bats or flying foxes, and the Microchiroptera. Bats come as small as 1.5 g with a wingspan of 15 cm (Craseonycteridae, Kitt's hog-nosed bat) and as large as the flying foxes in the genus *Teropus* (Teropidae), which may weigh up to 1.5 kg and have wingspans of 2 m.

The two suborders have long, independent evolutionary histories, although the very nature of their morphology, and in particular their fine, light bone structure, makes preservation unusual. In contrast to modern diversity, sufficient fossil material has been found to describe just more than 30 genera. The lack of fossil evidence has provoked repeated controversy and called into question whether bats are monophyletic or whether the fruit bats are actually more closely related to another group (primates are postulated because of shared evolution with megachiropterans of details of their neural pathways for vision). If this were the case, the remarkable flight structures would have to have evolved twice independently. Molecular data show relatively unambiguously that the two bat groups are monophyletic.

Bats are the only mammals capable of true flight (as opposed to gliding). The wing is formed by a thin membrane that stretches across the arms, elongated fingers, and along the body, forming a diaphanous umbrella-like structure, or patagium. Like all flying animals, bats need wings that are at once light but strong. The wings are greatly reduced in weight with muscles pulled in close to the body and bones reduced in size and volume. Torsional stress is reduced by simplification of joints. The remarkable flying abilities of bats ensure a global distribution, with bats often the only mammal naturally occurring on remote islands.

Whereas birds monopolize diurnal aerial niches, bats are nocturnal specialists. In some areas where birds and bats do not co-occur, bats may become more diurnal, providing thin evidence of competitive exclusion. Flying at night, visual acuity is of relatively little value; nonetheless, all but one species of Megachiroptera rely on vision to navigate. In contrast, microchiropteran bats have evolved navigational tools that are independent of sight. Using their larynxes, microchiropterans produce extremely high frequency sound that they emit through their nose or mouth. The sound produced by bats is referred to as ultrasonic because it is above the range that humans can hear. The ultrasound bounces off both potential prey and obstacles and is received back at the large, elaborated ears of the bat. Because the bat navigates using the sound that bounces back, this form of navigation is called echolocation.

Despite their high specific diversity, patterns of reproduction (in the few species that have been studied) all are

remarkably similar. Females carry their young with them while in flight, and this constraint limits bats to producing one, or occasionally two, offspring. Paternal care of offspring is rare; hence social systems tend to be promiscuous, with few lasting bonds between males and females. Bats tend to be highly gregarious, hanging upside down in roosts containing hundreds, thousands, and in rare cases hundreds of thousands of individuals. Caves, cliffs, and the eaves of large houses all provide appropriate roosting areas.

Bats are usually insectivorous, gleaning their prey while airborne, but the diversity of diets is enormous. Diet specialists cover a range of vertebrates and include species that are adapted to fish, much like a small eagle, frog eaters, blood-eating specialists (the vampire bats), nectar feeders, and two groups of specialized fruit eaters. Two families of bat dominate fruit eating: in the Old World, Pteropidae (flying foxes), and in the New World Phyllostomidae (spear-nosed bats). In the forests in which they live, fruit-eating bats are keystone species, dispersing many of the largest forest seeds and fruits. Of course, a frugivorous diet and the large aggregations in which fruit-eating bats can occur make some bats extremely unpopular with fruit farmers around the tropics.

Primates

In recent times, primates have been found on every continent and in every habitat on earth. If one excludes the most abundant and successful primate, humans (*Homo sapiens*), the range of the order is much reduced, with representatives found in the tropics and subtropics of Africa, Asia, and Latin America. One macaque species (*Barbary macaques*, *Macaca sylvanus*) is found in Europe on the island of Gibraltar across narrow straits from Africa. Another macaque species, the Japanese macaque, *Macaca fuscata*, survives in a temperate environment by relying on hot springs during the winter.

With the first fossil representation in the late Cretaceous of North America, primates are an ancient order. The modern order is represented by 15 families, including the apes, gibbons, marmosets, lemurs, and galagos. Just less than half of the familial diversity is found in the suborder Strepsirhini, or prosimians, which includes the five families of lemurs, all of which are endemic to the island of Madagascar, the Lorisidae (pottos and lorises), and the Galagidae (galagos), small nocturnal monkeys of Africa often called bushbabies. Some include the Tarsiidae as well.

The 40 species of lemurs show a remarkable range in size from 50 g (lesser mouse lemur, *Microcebus murinus*) to more than 10 kg (Indri, *Indri indri*) and a diversity of diet from generalized herbivores, insectivores, a larvae specialist (the aye-aye, the only extant species in the family Daubentonidae), and four species of bamboo specialist (Haplemur species). Many members of this suborder are under threat, victims of the rapid and seemingly irreversible deforestation of Madagascar.

Nineteen species in three genera of galago are recognized, an increase of eight species in the last decade. This change resulted from molecular analyses that showed that a single species of galago there may be contained several cryptic species, virtually indistinguishable morphologically from one another.

The remaining primates are placed in the suborder Haplorhini, which includes the eight families of New and Old World anthropoid primates and the tarsiers. Found across the forests of Southeast Asia, the tarsiers bear a strong physical resemblance to galagos and for many years were grouped with them in the prosimians. Genetic evidence performed in the late 1990s, and a reconsideration of morphological characters, place the tarsiers firmly as distant, but distinct, relatives of the anthropoid primates.

The extant South American primates fall into four families, the Cebidae (56 species, including tamarins, marmosets, capuchins, and squirrel monkeys), the Aotidae (eight species of night monkeys), the Pitheciidae (40 species, including tits, uacaris, and saki monkeys), and the Atelidae, (24 species, including howler, spider, miqui, and woolly monkeys). Marmosets and tamarins, placed in the subfamily Callitrichinae, are unusual in that all but one species regularly produces twins. They have a monogamous or polyandrous mating system (one female, several males), and a diet that is highly omnivorous and may include fruit, seeds, insects, and small vertebrates. Some species, including the diminutive pygmy marmoset (150 g), are exudate specialists, eating the gum of trees.

Many New World primates have been described as monkeys with five legs due to the extensive use they make of their prehensile tails, an adaptation not found in Old World monkeys. Body size ranges from just more than 500 g for squirrel monkeys (*Saimiri* sp.) up to 12 kg for the woolly spider monkey (*Brachyteles arachnoides*). The diet is predominantly fruits and other vegetation and competition for resources is common among cebids, with larger species dominating smaller ones. As a result, many smaller species have evolved diet or behavioral specialization, including nocturnal foraging (night monkey, *Aotus* sp.), the ability to eat green fruit (titi monkeys, *Callicebus* sp.), or habitat specialization (swamp living in uacaris, *Cacajao* sp.).

Old World monkeys in the family Cercopithecidae dominate the primates numerically, with 132 recent species in 21 genera. Found across Asia and Africa, cercopithecoid monkeys include animals with divergent life history strategies, sizes, and diets. The guenons, macaques, and baboons (subfamily Cercopithecinae) range in size from 1 to 50 kg and are usually found in large, extended matrilineal groups. Many species are tree-living, but the baboons and some macaques have adopted a terrestrial or semiterrestrial existence. Primarily fruit eaters, most species are omnivorous and will supplement their diet with practically anything that they can capture and eat.

The columbine monkeys, langurs, and leaf monkeys are placed in the subfamily Colobinae. A diverse group of animals, this group tends to be more arboreal and slighter than the cercopithecines. Although the evolutionary history of this group is mainly African, modern representation is dominated by Asian forms. Diet is reflected in an unusual stomach structure, with a large, saclike upper stomach that, like the rumen of ungulates, allows for fermentation of the coarse leaves that constitute much of this group's diet.

The 14 species of gibbons (family Hylobatidae, genera *Bunopithecus*, *Hylobates*, *Nomascus*, and *Symphalangus*) are commonly called the lesser apes and are often grouped together with the true apes, or Hominidae, in the superfamily

Hominoidea. Found throughout tropical Asia, gibbons are renowned for their brachiating (or swinging) locomotion and their echoing, eerie loud vocalizations. The family is primarily monogamous, and its diet is primarily fruit, supplemented with young leaves and flowers.

The best studied group of primates is the family Hominae. Formerly broken into two families, Pongidae (orangutans, gorillas, chimps, and bonobos) and Hominidae, data, particularly molecular genetic analyses, have made the isolation of human beings and their ancestors in their own family impossible. Although largely vegetarian (gorillas are almost exclusively folivores), some chimps have been known to actively hunt other monkeys and to kill conspecifics. Most species are extremely social, with the exception of orangutans, which tend to be solitary except when mothers are in association with young or during the mating season. Slow breeders and habitat specialists, great apes are declining in number and distribution as a result of the rampant expansion of their conspecific *H. sapiens*.

Carnivora

A diverse group of animals, the Carnivora share a key diagnostic feature. The carnivore dentition is typified by the evolution of a single pair of slicing teeth, the carnassials. Formed from the upper fourth premolar and the lower first molar, the carnassials are the key to understanding the diversity and plasticity of Carnivora. By isolating the shearing function to a single set of teeth, true carnivores have retained flexibility in their diet while allowing for specialization of shearing of meat. Molars retain their grinding function, whereas premolars in front of the carnassials are retained for grasping, crushing, or puncturing food. The canines are often elaborated into spikes of one size or another, allowing a sharp stabbing of prey. Although carnassials were critical to carnivore evolution, many extant members of the order have reverted to more generalized dentition and lost the carnassials (e.g., pandas grinding bamboo).

Modern carnivores are divided into two major groups, the Feliformia, which includes hyenas, felids, mongooses, and viverrids, and the Caniformia, a diverse group that includes seals, sea lions, walruses, canids, bears, procyonids, and the mustelids.

Pinnipeds are closely related to other carnivores, but there has been a running debate as to the relationship of the three families: the eared seals (Otaridae, 16 species, seven genera of eared seals and sea lions), the earless seals (Phocidae, 19 species and 13 genera of seals), and the walrus (Odobenidae, one species). For many years, these taxa were considered monophyletic, but a suggestion around the 1990s was made that they are diphyletic, with walruses and sea lions branching off from a common ancestor with bears and phocids (seals) being more closely related to the mustelids. More recent molecular and morphological work confirms the monophyly of the pinnipeds.

The Canidae include 35 species of foxes, wolves, jackals, and dogs. Ranging in size from the fennec fox (*Vulpes zerda*, just under a kilogram) to the wolf (*Canis lupus*, up to 80 kg), canids show a wide range of diet and social organization. The family is best known for its pack-living, social animals (wolves, the Asian wild dog or *Cuon alpinus*, the African wild

dog *Lycaon pictus*, and the South American bush dog *Speothos venaticus*), species that raise a single litter of pups communally and that are capable of hunting animals up to 10 times their body weight through coordinated group hunting. Most species, however, live in small family groups and subsist on rodents and small vertebrates. One species, the African social bat-eared fox (*Otocyon megalotis*), specializes on termites. Another species, the stilt-legged South American maned wolf (*Chrysocyon brachyurus*), is a solitary omnivore.

Mustelids, with 59 recent species in 22 genera, are among the most diverse of the modern carnivores. A family that includes weasels, badgers, and otters, Mustelidae are found from above the Arctic Circle to the tropical rain forests and on every continent except Australia. The group includes efficient terrestrial hunters of small mammals (mustelids, badgers) and species that are oceanic and specialize on bivalves for their diet (the sea otter, *Enhydra lutris*). Otters have become the dominant aquatic carnivore in many lakes and rivers across much of the globe. The giant otter, *Pteronura brasiliensis*, of the Amazon basin is the largest otter, weighing 30 kg, and is highly social, 'herding' fish to improve success of prey capture.

Absent from South America, the nine species of badger are mostly nocturnal omnivores of stocky build and with strong, sharp claws. The Eurasian badger (*Meles meles*), a highly social animal that lives in extended burrows or setts, is an earthworm specialist. Weasels and polecats are found from northern Greenland to the tip of Africa. Whereas the European weasel (*Mustela nivalis*) can be as small as 50 g, most weasels follow a remarkably common body form. Predominantly terrestrial and weighing 1–2 kg, with long tubular bodies and short legs, they get their speed from the compression–extension of the body; sharp teeth deliver a killing blow to a number of small vertebrates, such as frogs, rodents, rabbits, or birds. Some species once trapped for their fur are now raised in large commercial farms – e.g., mink (*Mustela* sp.).

The best known felid is the largest, the lion (*Panthera leo*). In many ways, the lion is an anomalous cat. Although most of the 40 species of cat are solitary hunters, the lion is a highly social, cooperative hunter. Even congeneric large cats such as the leopard (*Panthera pardus*, Asia and Africa), the tiger (*Panthera tigris*, Asia), the snow leopard (*Panthera uncia*, central Asia), and the jaguar (*Panthera onca*, South and Central America) are more similar in their social structure and hunting patterns (solitary, territorial, with male territories overlapping those of females) to the smaller cats in the genera *Felis*. All cats are highly carnivorous, but diet ranges from the largest bovid species to frogs, fish, and mollusks. Although most are nocturnal stealth predators, the cheetah (*Acinonyx jubatus*) is a true diurnal pursuit predator, capturing prey with bursts of speed of up to 90 km h⁻¹.

Viverrids (civets and genets) and mongooses (Herpestidae) are sometimes classified as a single family, although the most updated phylogenies separate them. Both families are exclusively Old World. Viverrids show a wide range of habits, many are truly arboreal, but there is a semiaquatic form (otter civet, *Cynogale bennettii*) and a terrestrial species from Madagascar that resembles a medium-sized cat (*Cryptoprocta ferox*). Mongooses are either solitary, nocturnal predators that resemble polecats or highly social, diurnal insectivores.

Cetacea

The discovery of Eocene fossil whales confirms an early branching of the Cetacea from the primitive ungulates, closely related to modern artiodactyls. The 11 families of whales, dolphins, and porpoises show a wide diversity of body size from the finless porpoise, *Neophocoena phocoenoides*, at 30 kg, to the world's largest mammal, the blue whale, *B. musculus*, at 150 metric tons. There is an equally large diversity of diet from tiny shrimp or krill to seals, fish, and squid – practically anything that swims. Social structure is variable and ranges from solitary individuals to the communal pods of the Orca, *Orcinus orca*, or killer whale, whose social system more closely resembles that of wolves than other whales. Cetaceans share many adaptations critical to true aquatic living. The skulls are 'telescoped,' with the premaxillary and maxillary bones forming the roof of the skulls and the occipital bones forming the back of the skull. In all whales the tail fin is horizontal.

Whales are divided into two suborders, the Mysticeti, or baleen whales, with 13 recent species in four families, and the Odontoceti, or toothed whales, which includes 71 species in seven families. Baleen whales, which include the aforementioned blue whale, are filter feeders. Incongruously, these leviathans live on tiny prey, from krill and small planktonic copepods, often less than 1 cm in length, to small, schooling fish. Migratory patterns across entire oceans from summer to winter feeding grounds are not uncommon, with many baleen whales being truly cosmopolitan species. Baleen whale populations, severely decreased by aggressive hunting during the nineteenth and twentieth centuries, are still in the process of recovering.

The toothed whales in the family Odontoceti are found in all oceans and all seas. Some of the smaller members of the family are also found in rivers and lakes on all continents except Australia. Like bats, the toothed whales all use echolocation, allowing them to hunt and live in turbid waters where visibility is low. Although echolocation 'pings' or clicks are used for locating prey, longer, more continuous tones are also important for communication among conspecifics. The toothed whales include three species of sperm whale, including the giant sperm whale (Physeter catodon, family Physteridae) made famous by Herman Melville in Moby Dick; six species of Phocoenidae, or porpoises, found throughout the Northern Hemisphere and in near-shore environments of South America; 21 species of the poorly known beaked whales (Ziphiidae), some of whose species have never been seen alive; and two species of highly gregarious Monodontidae, limited to the Arctic oceans, the beluga whale (*Delphinapterus leucas*), or white whale, and the narwhal (*Monodon monoceros*). The narwhal has a long, spirally grooved single upper tooth, used by males in intrasexual competition, which may provide the origin of the unicorn myth.

Sirenia

The five species of the families Dugongidae (with two species: the Dugong, *Dugong dugon*, and Steller's Sea Cow, *Hydrodamalis gigas*) and Trichechidae (with three species of manatee) are the sole modern representatives of the Sirenia. An anomalous, nearly hairless group of mammals weighing up to 1600 kg, the common name for these animals, 'sea cows,' is remarkably accurate. The only large, fully aquatic mammal

that lives on grasses, the sirenids have extremely long intestines. Like perissodactyls, cellulose fermentation takes place in the hindgut, enabling the sea cows to process large volumes of relatively coarse seagrass vegetation. Reproduction is both delayed and slow, with long interbirth intervals and the production of a single offspring that remains with its mother for up to 2 years.

Sirenids have a near-global distribution in tropical and subtropical waters. Manatees are found up the Amazon and in major river systems of West Africa. They suffer little competition for their main resource, aquatic grasses. Yet, despite this, all species are threatened with extinction. These large mammals are docile, represent a large package of meat to human hunters, and are supposed to taste good. This, combined with slow reproduction, has led to overharvesting throughout their range. Pollution, dam building, and injury from the propellers of motorboats all amplify the problems of overhunting.

Proboscidea

Elephants were widely spread across North America, Asia, and Africa until recent times. Throughout the Tertiary, proboscideans showed a relatively wide range of adaptations and a diversity of species. Today, only three species remain: the African bush and forest elephants (*Loxodonta africana* and *Loxodonta cyclotis*, respectively) and the Asian elephant (*Elephas maximus*). These hulking creatures are the largest terrestrial mammals, weighing up to six metric tons. Although the Asian elephant is now limited to the forest of Asia, this probably reflects a historical shift from open grassland and woodland habitat, which has now almost universally been converted to human agricultural use. In Africa, elephants are found throughout the forests, woodlands, and savannas, but at highest densities in savanna woodlands. Some ecologists believe the split of the two African elephants, once defined as subspecies, reflects a more recent fragmentation of populations, with a former, clinal structure of genetic variation now lost.

In both Africa and Asia, elephants are ecological keystone species, one of the few species, other than humans, having a direct impact on the form and structure of the environment in which it lives. Elephants keep savanna ecosystems from reverting to woodland when they knock down trees. 'Catastrophic' destruction of trees may occur in droughts but is clearly part of a long-term natural cycle. In Asia and Africa, the fruits and seeds eaten by elephants are transported and then defecated, seeding the plains and the forests and depositing the seeds in their own fertilizer.

Elephants, fossil and modern, have a highly specialized dentition with six cheek teeth on either side of the jaw. At any one time, one to two teeth are exposed in the jaw. As these teeth wear down, they are replaced by a tooth erupting from behind the current tooth. This pattern of sequential replacement of grinding teeth is unique in mammals. Tusks are formed from elongated upper incisors.

Highly social, female elephants live in extended, matriarchal groups. Adolescence is prolonged, with males remaining in the herd until they are 10–15 years old and females not breeding for the first time until they are 15 years old. Males are solitary, and breeding priority is determined by an

interaction of sheer size (which increases indeterminately with age) and an endocrinological sexual state called musth. Found in both elephant species, musth is associated with heightened testosterone levels and makes males extremely aggressive. The length of musth increases with age, amplifying the reproductive success of older, larger males.

Elephants have been hunted for their ivory, and in several populations in Uganda and southern Africa, tusklessness in females and reduced tusk size in males have occurred as a result of repeated selection through hunting. In the long term, the greatest threat to elephants is loss of habitat and conflict between man and elephants. But poaching for ivory, which has been cyclical, peaking in the early twentieth century, and again in the late 1980s, showed some decline in the 1990s and the early part of this century. However, particularly in Central and eastern Africa, poaching has again increased sharply and is an immediate threat to elephants.

Perissodactyla

If you are interested in horses, tapirs, and rhinos, the mid-Tertiary was the time to be alive. Although modern perissodactyls are represented by only eight species of equid in one genus (*Equus*), four species of tapir in one genus (*Tapirus*), and five species of rhinoceros in four genera, this represents but the faintest hint of the diversity of this order in the past. Of 14 Cenozoic families, only three families and six genera are represented in the modern mammalian fauna.

Modern equids all look very similar: highly cursorial with a single hoof and consistent compact body, long neck, and highly hypsodont dentition in a large jaw with a distinct gap or diastema. Modern equids are only found in Africa and Asia, although there is evidence of the historical extinction of the tarpan, or European wild horse. Equids went extinct in North America in the Pleistocene, but asses and horses have been reintroduced in many parts of North America, the center of evolution of the Equidae. In contrast, the Pliocene of North America was populated with a few low-crowned, three-toed equids and three-toed horses, hypsodont species of various sizes, from the small, gracile *Nannippus* species to the larger *Hipparion* species. The first one-toed horse, *Pliohippus*, lived side by side with the hippo-like rhino *Teleoceras*, whereas in Asia the elephant-sized rhinoceros, *Sinoitherium*, coexisted with the hippo-like rhino *Chilotherium*.

Only two forms of social organization are seen in modern equids. Those species that live in relatively arid environments, the asses and the Grevy's zebra (*Equus grevyi*), exhibit flexible associations among females and male territoriality. Females move widely in search of food and water, whereas males tend to aggregate around water holes, the limiting resource. Mating is promiscuous. In contrast, horses and the two remaining zebra species, the mountain zebra, *Equus zebra*, and the plains zebra, *Equus burchelli*, form harems of unrelated females and a single male, a social structure also seen in gorillas.

All five species of rhinoceros are threatened with extinction, the victim of the value of their horn. Two uses of rhino horn have been identified: shavings of the horn are used in traditional Asian medicine to bring down fever, whereas in Yemen, the highest value has been placed on dagger handles made from rhino horn. Income from a booming oil economy in the 1970s led to increased demand from Yemen, whereas

economic growth in Asia in the 1980s and 1990s made rhino horn, always expensive, accessible to many more people, thus increasing demand. The black rhino (*Diceros bicornis*) was found widely across eastern and southern Africa until the late 1970s, now all but extinct except in reserves and conservancies. The white rhino (*Ceratotherium simum*), almost extinct in South Africa at the turn of the century, has recovered to where populations number 10,000, but a recent surge in poaching again threatens the species. Outside of South Africa, however, the northern subspecies is probably extinct, and introduced populations in Zimbabwe were decimated in the early 1990s. The Sumatran rhino (*Dicerorhinus sumatrensis*) and the Javan rhino (*Rhinoceros sondaicus*), formerly found across Southeast Asia, are also hanging on by a thread. Of Asian species, only the Indian rhinoceros (*Rhinoceros unicornis*) exists in any numbers, and only as the result of major conservation efforts.

Hyracoidea

Modern hyraxes are classified in a single family with three genera and four species. Limited to Africa, fossil hyraxes are also found in the Middle East and Europe. Although modern forms are all more or less rabbit-sized (2–5 kg) and resemble a very large guinea pig, some extinct forms weighed up to 50–70 kg. Tree hyraxes (*Dendrohyrax* sp.) are entirely arboreal, whereas both bush hyraxes (*Heterohyrax brucei*) and rock hyraxes (*Procavia capensis*) live on talus slopes, rock outcrops, and cliffs. Affiliations with other animals are uncertain, although it appears that hyraxes represent an early branching from ungulates, perhaps sharing an early evolutionary history with elephants.

Tubulidentata

Found across most of sub-Saharan Africa, the nocturnal and solitary aardvark (*Orycteropus afer*) is the last survivor of the Tubulidentata. Never a very diverse order, the majority of the aardvark's evolutionary history is in Africa and Europe, although aardvarks are known from Asia. Aardvarks weigh about 50 kg and resemble pigs with extremely long snouts, large ears, and long fleshy tails. Like most animals specialized for eating ants or termites, aardvarks have long, sticky tongues that are used to collect their prey. Powerful arms, with large claws, are used to excavate burrows and search out food.

Artiodactyla

The decline of the perissodactyls coincides with the rise of the artiodactyls. Starting in the Miocene, artiodactyls showed a remarkable diversification of families, many of which are still extant. Of 36 families found throughout the Cenozoic, 10 families and 89 genera are still found, with a near-global distribution in North and South America, Europe, Asia, and Africa. Found in all habitats, from the far north of Greenland to the southern tip of Tierra del Fuego, artiodactyls are clearly the most successful of the extant ungulates.

Diagnostic characters of artiodactyls are found in both hard and soft tissues. All members of the order have two- or four-toed hooves, with a plane of symmetry passing through the third and fourth toes. In four families (Suidae, Hippopotamidae, Tragulidae, and Tayassuidae), four fully functional

digits are present, although peccaries have reduced digits on the hind limbs. All limbs have springing ligaments that capture energy when the leg flexes and return the energy to the foot as the limb pushes off, thus increasing efficiency of locomotion.

Previously categorized in the suborder Ruminantia, six families now stand separate: Tragulidae, mouse deer; Giraffidae, giraffes and okapis; Moschidae, musk deer; Cervidae, deer; Antilocapridae, pronghorns; and Bovidae, cattle, sheep, goats, and antelopes. They were previously grouped together because they are all typified by ruminant digestion, in which the rumen, an expanded first segment of a four-chambered stomach, provides an environment for the bacterial digestion of cellulose. This allows the animal to make use of highly siliceous grasses and vegetation. The cell contents, liberated by digestion in the rumen, and dead bacteria are digested farther along in the intestines. Ruminants also typically lack upper incisors, with lower incisors used to scrape grasses against the maxilla.

The family Tragulidae is represented by eight species in three genera, containing chevrotains, or mouse-deer. These small, primitive ungulates are found in the forests of Africa, southern Asia, and Southeast Asia. Weighing 3–12 kg, the family lacks horns although the upper canines are unusually large and grow continually. Canines are used in intrasexual competition by males and may be used in antipredator defense by both sexes.

Cervids, or deer, are found across the Northern Hemisphere, in most of South America, and in the northern fringes of Africa. The family is absent from sub-Saharan Africa, perhaps excluded by the remarkable radiation of the antelope fauna in that region. Antlers are a defining character and are found in almost all of the 51 extant species. With the exception of caribou, only males carry antlers. Unlike horns, antlers are grown and shed annually. Antlers are found in a variety of forms, from spike or stubs to the elaborate branched and palmate forms seen in the moose (*Alces alces*). Deer are found in nearly every biome, from the snowfields of the Arctic, where they subsist on lichen, to the tropical forests of South America and Asia, where fruit is a common dietary staple.

The seven species of musk deer in the Moschidae family are found in central Asia, the Himalayan plateau, and east through parts of China and Vietnam. A primitive deer, the family was originally subsumed under the Cervidae. Lacking antlers, they have sharp, swordlike upper canines, similar to those found in the chevrotains. Musk is produced by a gland in its abdomen. This waxy substance is used as the base for many expensive perfumes and demand has led to near extirpation of all members of the family across much of its range. Although captive breeding of musk deer by the Chinese might reduce demand on wild populations, prospects are not good for these animals.

Antilocaprids are only found, and have only been found, in North America. Although the family has a long and relatively diverse fossil history, only one species (*Antilocapra americana*) survives. The horns of the modern species are relatively simpler than the much more elaborated fossil forms. Unlike giraffids and all bovids, *Antilocapra* sheds its horn sheath annually, much like a deer losing its antlers.

The Giraffidae were more speciose during the mid-Tertiary and are represented in modern times by only two species, the giraffe, *Giraffa camelopardalis*, and the okapi, *Okapia johnstoni*. The family, exclusively Old World, has a long fossil history in Europe, where the modern genus *Giraffa* is first found in the Pliocene. Having evolved in Europe, giraffes dispersed to Africa. Whereas modern forms have two, short stubby horns, fossil giraffes such as the genus *Giraffokeryx* had four long horns. Camel-like forms, resembling more closely the modern okapi, were also found in Europe.

By far the most diverse of the ruminants is the family Bovidae. With 50 genera and 143 species, the family includes the greatest radiation of modern herbivores. Bovids are more widely dispersed than any other ungulate family, with a near-global distribution, absent only from Australia and the oceanic islands of Asia. But it is in Africa that the family has its greatest diversity. Members of all subfamilies are found in Africa, including 18 species of duiker (Cephalophinae, exclusively found in Africa); 26 of 38 species of 'true' antelope (Antelopinae), all 10 species of hartebeest, wildebeest, and topi (Alcelphinae), all but one of the eight species of grazing antelopes, including oryx (*Hippotragus*), all eight species of floodplain-dwelling antelopes, including waterbucks and reedbucks (Reduncinae), and the one species of impala (*Aepycerotinae*). The only subfamilies of the Bovidae that are relatively poorly represented in Africa are the Bovinae (10 of 24 species: African buffalo, eland, and *Tragelaphus* sp.) and the sheep and goats of Caprinae (three species in North Africa, none south of the Sahara, of the total 35).

The suids, peccaries, and hippos make up the last of Artiodactyls. Despite their global distribution, wild pigs and boars (family Suidae) are an Old World family, with feral populations introduced into North and South America, Australia, Tasmania, and New Guinea. They range in size from the pygmy hog (*Sus salvanicus*) of the Himalayan foothills (9 kg) to the giant forest hog (*Hylochoerus meinertzhageni*) of central and East Africa (275 kg). With 19 species in five genera, there are relatively few modern pig species, all of which closely resemble the domestic hog. Omnivores, pigs usually are forest dwellers, although the warthog (*Phacochoerus aethiopicus*) is found throughout the savanna woodlands and grasslands of Africa. Lacking horns, the upper canines of most pigs are ever-growing and form large, slashing tusks. This adaptation has gone to its extreme in the island endemic, the babirusa (*Babirusa* sp.) of Sulawesi and other small islands in Indonesia, whose tusks curl up over the head.

Closely related to the pigs are the three monotypic genera that represent the extant peccaries (family Tayassuidae). Thought to be derived from Old World pigs and with a fossil record in the Old World and New World, the peccaries are South America's pig equivalent. Smaller than pigs (20–40 kg), peccaries are critical frugivores and seed eaters thought to be important for seed dispersal in South America's tropical forests.

The Hippopotamidae family includes the two species of extant hippos, the hippopotamus (*Hippopotamus amphibius*), found in Africa from the Nile basin south throughout West, East, central, and southern Africa, and the pygmy hippo (*Choeropsis liberiensis*), found only in a small section of West Africa. Recent fossil hippos are known from Madagascar, and

in the Miocene, the family was spread throughout Africa and Asia. The hippo is a nocturnal grazer, leaving rivers and lakes at night to forage along their banks.

The first fossil remains of the Camelidae, the family that includes camels and llamas, are in the Old World, although by the Eocene there are camelids in the fossil record of the Americas. Former diversity was much greater than that of the present, where only species remains in each of the Lama and Vicugna genera, both found in South America, and two Camelus are found in the Old World: the dromedary (*Camelidae dromedarius*, southwest Asia and North Africa) and the Bactrian, or two-humped, camel (*Camelidae bactrianus*, Mongolian steppe). Camels are highly adapted for desert life. The feet are splayed to prevent the large (650 kg) animals from sinking into the sand, a reversal of the usual ungulate simplification of foot structure that is evident in the South American camelids and most fossil forms. Water conservation is achieved through well-insulated bodies, a high tolerance for dehydration, dry feces and concentrated urine, and metabolic conversion of fat (stored in the hump).

Pholidota

Pangolins, also called scaly anteaters, are not very diverse – eight species in a single genus, *Manis* – yet they have a wide geographical range, occurring in a variety of habitats across southern Africa and in much of Southeast Asia. The order is also found in the Tertiary fossil record of all continents except Australia and Antarctica. Resembling a cross between an armadillo and an anteater, pangolins are large (5–35 kg) and both ecologically and culturally important. The scales, which cover the body completely, may constitute up to half the animal's body weight and are prized for their medicinal value across Asia, although no evidence exists that the scales, which are composed, like rhino horn, of agglutinated hair, have any therapeutic value. This has not presented rapid, and extensive, overharvesting across Southeast Asia, with the market now turning to Africa as source populations are depleted. Pangolins have the distinction of being the only extant mammals with no teeth.

Rodentia

The diversity of the order Rodentia deserves a volume of this encyclopedia of its own. With nearly half of all mammalian species (2277), nearly 500 genera, and 33 families, rodents are the most successful group of mammals living today. Two families, Muridae and Cricetidae, previously bound as one before recent analysis of molecular data, represent roughly two-thirds of the living species (hence, one-third of all mammals). Muridae's 730 species, subdivided into five subfamilies, along with Cricetidae's 679 species, subdivided into six subfamilies, includes rats, mice, squirrels, guinea pigs, beavers, kangaroo rats, dormice, jerboas or jumping mice, hamsters, mole rats, porcupines, chinchillas, agoutis, and nutria. Rodents are used by humans for food (e.g., guinea pigs), fur (nutria, beaver, chinchilla), and pets. Most rodents weigh approximately 100 g and have relatively similar body plans: long nose, large eyes, and long tails. Size varies in four orders of magnitude, however, with the smallest member

of the order weighing about 5 g (pygmy mouse, *Baiomys* species of Central America) whereas the largest, the capybara (*Hydrocherus hydrochaeris*), may weigh up to 60 kg and is found near water across the northeast of South America.

Rodents are an ancient order of mammals, found in the Paleocene of both North America and Asia, indicating an earlier first occurrence. Rodents have always been successful, and myriad fossil forms are found in the Eocene of Asia and North America. Modern rodents are usually divided into three major groups: the cavy-like rodents, or Caviomorpha; the mouse-like rodents, the Myomorpha; and the squirrel-like rodents, the Sciuromorpha. Although a convenient division, both paleontological and molecular data suggest that this tri-partite classification may be more useful than it is real.

While supporting a phenomenal diversity in both Recent species and fossil forms, all rodents have adopted a similar jaw structure, diagnostic of the order. The incisors are used for gnawing and clipping and are sharp and ever-growing. Molars are adapted for grinding. The jaw musculature is also modified, with the muscles moving some of their attachments off the zygomatic arch and cranium forward onto the rostrum, with chewing thus providing a forward movement of the jaw.

Rodents have a global distribution and are found in every habitat type from the high Arctic to the driest deserts and the wettest tropical forests. Species like the Norway rat, *Rattus norvegicus*, have hitched rides on ocean-going vessels since people started sailing the seas 10,000 years ago. A crop pest, the Norway rat, is globally distributed and causes for billions of dollars of damage each year. Of greater historical significance, rats have acted as secondary hosts for a number of diseases that plague humans, including the bubonic plague itself, which killed 30 million people in Europe from the fourteenth to seventeenth centuries. Rats have also been one of the main agents of island extinctions.

Lagomorpha

Rabbits (Leporidae) and pikas (Ochotonidae and Prolagidae), although not diverse when compared to the rodents (92 species in 13 recent genera), are nearly worldwide in their distribution. Found in both the New World and Old World, rabbits naturally occur on all continents except Australia, where they have been introduced, as they have been to many larger islands around the world. Fossil remains are first found in Paleocene China, and they occur in a wide variety of habitats, from the Arctic snowshoe hare (*Lepus americanus*) to the tropical species of the genus *Nesolagus* (the Sumatran and Annamite rabbits). Rabbits are herbivores, with hypsodont molars, and, like rodents, ever-growing incisors are used to clip vegetation. Body size varies over a relatively narrow range (300 g to 5 kg), and body form is consistent: round heads, large eyes, big ears, and extended, ricochet hind legs, which converge on those of macropod marsupials. Pikas, which are smaller than rabbits (approximately 200 g), closely resemble small caviomorph rodents and are most commonly found on rocky outcrops and talus slopes. Pikas are found in North America along the northwest coast and across the central Asian steppe into Russia.

Macroscelidea

The taxonomic position of the elephant shrews is unclear. Similar to kangaroo rats with long noses, with only 15 living species and a poor representation in the fossil record, the order is usually grouped with the lagomorphs and rodents, although earlier taxonomies have suggested an affiliation with insectivores. Found only in Africa, the order has a narrow range of body size, from the tiny 45-g short-eared elephant shrew (*Macroscelides proboscideusi*) to the rather larger 500-g golden-rumped elephant shrew (*Rhynchocyon chrysopygus*). Absent in West Africa, elephant shrews occupy a diversity of habitats, from the deserts of Namibia to the lowland forests of central Africa. Despite the diversity of habitats occupied, all species are monogamous, terrestrial, and omnivorous, although insects form a large part of their diets where studied.

Evolutionary Trends

Evolution of Brain Size

The defining characters of hominid evolution are an upright gait and an increasing large and complex brain. Humanoids have the largest brain for their body size of any mammal, extant or extinct. Brain size has, not surprisingly, been correlated with intelligence, with other relatively large-brained forms (e.g., dolphins and great apes) being imputed to be more intelligent than the smaller brained mammals. If larger brains do, indeed, confer greater intelligence and survival of an individual is in some way correlated with intelligence, then one would predict strong selection for increasing brain size in mammalian lineages.

At some point in each of their fossil histories, progressive increase in brain size is observed in primates, cetaceans, carnivores, and ungulates. However, increasing brain size has not been a linear effect, but has been punctuated with periods of rapid increase followed by stasis or relatively slow rates of change. Rapid evolution of brain size occurred early in primates, with modern prosimian brain size occurring by the late Eocene. In anthropoids, long held as the best example of progressive evolution of brain size, a rapid increase in brain size in the Oligocene was followed by relative stasis in most lineages, with the exception of the hominid line. Because carnivores, ungulates, primates, and whales have some of the largest brains and are also among the more charismatic species, generalization about the occurrence of progressive brain size evolution in mammals through time may result from a certain large mammal myopathy.

In many lineages of mammal there has been no such progressive increase in brain size – marsupials, edentates, and some lineages of rodents have shown little change in relative brain size since the orders are first seen in the fossil record in the early Tertiary. This stasis is often attributed to differences in predator pressure, with Miocene South American and Australian marsupials not requiring ‘higher’ brain function and hence there having been no evolutionary pressure on brain size. This explanation is unsatisfactory given the high variation in brain size when evolution occurs in different mammalian lineages.

Because brains tend not to shrink in evolutionary time, the variance in brain size will increase with time, and hence any increase in variance, with size bounded at the lower end of a distribution, will result in a larger average brain size. If selection in evolutionary time for increased brain size in different lineages reflects modern patterns of brain size variation, then examining the ecological and social correlates of brain size variation may give us an insight into the selective forces that may have shaped brain size. For instance, growth of the cerebellum has been correlated with locomotion in three dimensions (flight, swimming) as compared with terrestrial motion. Elaboration of the neocortex has been associated with various aspects of learning. Taxa that have prolonged periods of maternal dependence, and presumably long periods of information transfer, have relatively greater neocortex development than taxa with minimal parental association. Within lineages, in monogamous species males and females have similar brain structure, whereas in those species where males are promiscuous, there is elaboration of the hippocampus, the part of the brain correlated with spatial memory. The hypothesis is that in searching for receptive females, promiscuous males search over large areas, thus requiring greater spatial skills.

Cope's Rule

One of the earliest rules applied to mammalogy is Cope's Rule: species within a lineage will show increasingly large body size through evolutionary time. Cope made his findings in the late nineteenth century working on North American fossil assemblages (some of the best preserved of the Tertiary fossil record), yet most studies since Cope have failed to find support for this generalization. Some have argued that because most lineages originate at small body sizes, it is axiomatic that the only place they have to go is up. Others have stated that the pattern seen in the fossil record is a statistical artifact, the result of passive diversification of species within clades rather than the result of any kind of directed evolution. Recently, it was even suggested that although Cope was an advocate of directed evolution, he did not even do any significant analysis of body size trends and that the attribution of the first observation of this phenomenon is misplaced.

As with all paleontological examination, the detection of such trends relies on the quality of the data set used. Most studies of Cope's law have suffered from either a telescoped time frame or data sets that cover a long time run, but focus on a small number of taxa. But a recent study of Cope's law, which used a data set of 1534 species of North American mammals ranging in age from the late Cretaceous to the Pleistocene, suffers from neither of these faults. Species within a genus were followed through their evolutionary histories, and, on average, new species were 9% larger than the older species within the same genus. Diversification in size was not gradual, but changed rapidly at the Cretaceous/Tertiary (K/T) boundary, coincident with the rapid ordinal diversification of mammals. Average body weight of 29 species in the late Cretaceous was 150 g; by the early Tertiary, the average weight of 33 matched species was just more than 1000 g, an order of magnitude higher. There is an unambiguous directional trend to larger size in North American mammals, but what could possibly explain this trend?

Although data convincingly show that Cope's law is valid, at least for North American taxa, no good explanation has been offered as to why such persistent increases in body size are observed. Not only does body size increase within lineages, but at some point the middle of the size distribution drops out as well, leaving relatively large and relatively small species. This has led some to suggest that there are, perhaps, optimal body sizes for homeothermic mammals. Scientists have noted in modern assemblages of mammals that there are a disproportionately large number of species that weigh about 100 g (coincident with the average weight of Cretaceous mammals) and that this might be a lower end optimal body size for mammals. This hypothesis is supported by data on the relationship between minimum home range area and body size. While home range size scales roughly with body size in mammals, the relationship is U-shaped, with smaller mammals requiring relatively larger areas than expected. An 'optimal' body size is one in which a minimum area is required to support the activities of an individual (the bottom of the U-shaped curve): this minimum occurs between 80 and 200 g.

Upper end optima are not well defined, and gaps in the body size distributions of extant North American mammals are more illusory than real and are easily explained by random statistical variation. If Mesozoic and Cretaceous mammals were competitively excluded by dominant terrestrial vertebrates, the extinction of the dinosaur fauna at the K/T boundary may have opened up the larger end of the body size distribution, allowing mammals to evolve to larger sizes. If larger mammals show higher rates of extinction or lower rates of origination, gaps will develop in the upper end of the mammalian size distribution, perhaps mimicking the random body size gap distribution observed in an ecological time scale and allowing new taxa to continue to evolve to larger sizes.

The Island Rule

When mammals colonize islands, a strange thing happens: small mammals, such as rodents, tend to increase in size, whereas larger mammals, such as carnivores, lagomorphs, and artiodactyls, tend to become smaller. Numerous examples of dwarfism and gigantism have been found in the fossil record and can be documented in extant species, the most notable being the discovery of fossil evidence of pygmy elephants on Mediterranean islands and fossil remains of dwarf mammoth on the Channel Islands of California.

Explanations for this Island Rule have been numerous, and none is completely convincing, but for the most part they focus on a combination of resource limitation, reduced competition as a result of a depauperate fauna, and predator release. For larger species, a limited food supply would favor a smaller body size as individuals of smaller body size require fewer resources, can reproduce more efficiently, and are more likely to leave surviving offspring. Niche partitioning through character displacement will result in selection for the smaller competitor in a feeding guild to become yet smaller. Therefore, it is not surprising that the absence of the larger competitor results in an observed larger body size in the smaller species of a feeding guild. Predation has been hypothesized to have two different effects: in larger mammals, where size is a form of

predator defense, release from predators may select for reduced body size. This argument, of course, is confounded with the explanations provided by resource limitation arguments. For smaller mammals, where stealth and crypsis are defense strategies, absence of predators may reduce the adaptive value of small size, thus allowing small mammals to evolve to larger sizes.

A combination of bioenergetics and hypotheses put forth for Cope's Rule may provide a somewhat more synthetic argument for the Island Rule. Studies of mammalian feeding guilds suggest that within a guild of large-bodied mammals, the individuals of smaller species frequently monopolize a greater proportion of the available resources. In guilds dominated by smaller mammals the opposite appears to be true: individuals of larger species within the guild appear to control a greater proportion of the available energy. If there is an optimum size for mammals, arrival on an island in which there was release from predators and guild competitors would allow rapid evolution toward that optimum. Animals that were significantly larger, or smaller, than the optimum would show the greatest divergence between insular and continental body size.

These Legs Are For Walking: Predators and Their Prey

The evolution of ungulate locomotion, as typified by the evolution of the equid leg, is a topic covered by every high-school textbook. Cursorial specialization has evolved independently in a number of mammalian lineages, but there is a general pattern of morphological changes that results from a simple calculation: for an animal to move faster, it must increase either the length of its stride or the number of strides it takes. Hence, shifts in morphology must make the leg longer, faster, or both. The lateral reduction and fusing of bones (especially the hand and foot bones, the metacarpals, and metatarsals), the elongation of limbs, the reduction or loss of the clavicle, and the shifting of muscle mass toward the torso with a concomitant increase in the use of tendons to move the limbs are all part of the suite of changes that improve running speed.

Like their herbivore prey, carnivores have also evolved increasingly long-legged, faster forms through time. Carnivores have gone from being short-legged, small creatures to the long-limbed, slender-bodied forms typified by modern pursuit predators such as the cheetah or wolf. These forms appear to have relatively short evolutionary histories, with repeated evolution of similar body types in different carnivore lineages.

The coevolution of faster herbivores and faster predators has been described as a predator-prey arms race: slight increases in prey speed lead to higher rates of survival of those swift individuals who pass on their genes at disproportionate frequencies. Similarly, faster predators have greater hunting success, produce more offspring, and are better represented in successive generations. There is only one problem with this scenario: the fossil data do not support the hypothesis. Ungulates have tended to evolve ever more cursorial forms throughout the Cenozoic, beginning 55 million years ago in the Eocene. But it was not until the Pliocene, only 5 million years ago, that carnivores 'caught up.' By this time, most of the 'novel' ungulate adaptations for speed were tens of millions of years old.

Long legs confer the ability to move quickly, but what if this ability were a secondary adaptation, the result of selection for another phenomenon? An alternative explanation for cursorial adaptation suggests that the suite of adaptations that has evolved in ungulates has to do with the energetics of movement rather than the energetics of being eaten. All the observed adaptations do one of two things – increase stride length or reduce the costs of moving the leg. Hence, long legs lead to increasing efficiency of movement, whether the animal is walking 10 km to get to a water hole or dashing to get away from a predator. If the opening of the savanna led to increased distance movement in ranging patterns, long, simplified, lightweight legs would confer a great advantage in terms of energy efficiency of movement, whether daily or migratory.

Convergent Evolution

Mammalian evolution has been rich with novelty, whether in the evolution of flight in bats, the suite of adaptations evolved by whales that have brought mammals into the sea to live, or more specifically in one lineage the well-developed venom gland found in the hind legs of the platypus. Throughout mammalian evolutionary history, however, some of the more remarkable evolutionary patterns have involved the repeated evolution of derived characters in widely divergent mammal lineages. Convergent evolution spans a wide array of adaptations, from the suite of carnivorous Miocene South American marsupials that resemble extinct and contemporaneous placental carnivores to the striking similarity of burrowing forms in the marsupial mole (family Notoryctidae), the golden moles, (family Chrysochloridae), and true moles (family Talpidae).

Throughout their evolutionary history, mammals have shown trends to increasing specialization in many morphological and correlated ecological functions. For instance, as grasslands became widespread in the Miocene, ungulate tooth morphology shifted from a dominance of low-crowned, or brachyodont, teeth, which are easily ground down through the animal's lifetime, to a dominance of hypsodonty, or high-crown teeth, which last longer when an animal eats siliceous grasses covered in dust and dirt. This evolution has been complemented by an increased complexity of molar teeth to enable herbivores to more thoroughly grind their food. This pattern is observed in both artiodactyls and perissodactyls. Rodents have solved the problem differently, evolving ever-growing teeth, whereas proboscideans roll their teeth out of their jaw, each tooth having a limited useful life.

Convergent evolution may address the same problems but find different solutions. The expansion of grasslands and a high-cellulose diet have led to two different solutions to digesting an essentially indigestible substance. Ruminant digestion, widespread in the artiodactyls, uses the fore-gut, or rumen, as a fermentation chamber in which bacteria break down cellulose, making the grass cell contents available for absorption and converting the cellulose into digestible material. Because the passage of materials through the rumen limits intake, artiodactyls tend to be relatively selective, choosing grasses of high quality. In perissodactyls and some

kangaroos, a similar solution has evolved – bacterial breakdown of cellulose – but the site of bacterial digestion is in the hindgut and the process is less efficient. Although this means that hindgut fermenters cannot draw out as many nutrients from a given pulse of food, by rapid processing of food, hindgut fermenters can gain sustenance from larger volumes of lower quality forage.

Table 3 lists a few of the more widespread patterns of convergent evolution in mammals.

Geography, Biogeography, and Biodiversity

Gradients of Species Richness: Diversity, Density, Range, and Rapoport's Rule

The tendency for species richness to increase with decreasing latitude was first observed by Alfred Russell Wallace and has been the subject of significant study. Mammals, as well as nearly every taxa studied, appear to show this pattern (Safi *et al.*, 2011). Although nearly a dozen hypotheses have been suggested to explain the phenomenon, no single explanation appears dominant.

In a study of nearly 200 North and Central American mammals, which matched subspecies living at lower and higher latitudes, it was found that those living at lower latitudes had significantly smaller overall latitudinal geographical distributions. The same pattern is observed in a review of 679 North American mammals in which latitude is compared to the range of the species. In this study, in addition to the increase in range size with increasing latitude, a similar pattern is observed in a west-to-east gradient of longitude, with range sizes increasing to the east. Between the tropics and the northern Arctic regions, the average range of a species increases by a factor of 30. Interestingly, this same pattern is not observed in Australian mammals. The continent has a divergent geographic structure, with an arid center fringed by moist mountains, creating habitat diversity (and stability) very different from that observed in northern continents.

The vast majority of North American mammals have a narrow geographical species range that covers but a few habitat types and appear to be habitat specialists. Not surprisingly, patterns of variation are not consistent across orders, with the ranges of carnivores and artiodactyls being larger, on average, and bats and rodents much smaller. Nonetheless, the observed pattern of increasing range with increasing latitude is not an artifact of taxonomy: these patterns are seen both across all mammals and independently within mammalian orders.

Overall, range size shows a log-normal distribution, with very large and very small ranges being exceptional. Species with small ranges would probably result in a greater risk of extinction through severe catastrophic events such as abnormally cold, hot, or dry weather, through disease, or because of predation or competition. Species with unusually large areas may be prone to extinction because of the low densities at which they occur and the high probability that somewhere within their range they will come into conflict with humans.

It has long been noted that species diversity (or more accurately for mammals, species density, the number of species per unit area) decreases with increasing latitude. But

Table 3 Examples of convergent evolution in mammals

<i>Geographic location</i>					
<i>Adaptation</i>	<i>Holarctic</i>	<i>Africa</i>	<i>Madagascar</i>	<i>South America</i>	<i>Australia</i>

Asterisks indicate extinct taxa.

species density across a continent also has a strong trend, with species density increasing from east to west. The increase in density is greatest in the more southerly latitudes (30–40°) and correlates with increasingly complex topography, and hence greater habitat diversity.

Is there a connection between these two patterns, with narrowly distributed species packed in more closely at southern latitudes and in more complex habitats? Selection for wide tolerances of temperature and moisture extremes is more likely to occur in the temperate zones, where

temperatures can range from freezing or subfreezing in the winter to 35 °C in the summer. Patterns of climatic variation are similar over large areas; hence moving from place to place does not usually expose an individual to temperature or moisture extremes that have not previously been experienced. At more northern latitudes, the range of extremes of moisture, temperature, and light become more extreme, and unless a species is migratory, an individual will be exposed to these extremes year after year throughout its lifetime.

Although wide climatic tolerance might have few costs, it would confer few benefits in the tropics. In the tropics, the range of climatic variation at any given location is low. Microhabitat variation operates over a smaller spatial scale; hence staying in one place does not expose an individual to climatic variation, but moving a few tens of kilometers, or a few hundred meters in elevation, can expose an individual to conditions to which the individual, or its ancestors, have not been exposed. This has prompted one scientist to note that "mountain passes are higher in the tropics." The physical structure of such passes is, of course, no different in the tropics. But the perception of a dispersing animal trying to cross that pass may vary widely, depending in large part on the way adaptation for extremes in temporal variation of ecological variables has equipped the individual to deal with new microclimates encountered on its journey.

The most recent richness measures support the classic latitudinal gradient observation. Climate, however, impacts species diversity and functional diversity differently: for example, tropical climates generally have a lower functional diversity. Assuming stable environmental conditions, this is most likely because each niche experiences higher levels of 'occupancy,' in turn allowing for higher levels of species diversity. If phylogenetic diversity represents the amount of evolutionary time shared by a group of different species, and functional diversity represents the amount of species that share similar traits within a particular habitat or community, then it follows that the comparison of the two will reveal the importance of historical and evolutionary processes relevant to current richness patterns. This is the current line of thinking.

Hot Spots of Species Richness and Endemicity

Broader patterns of species diversity and species density may explain large-scale geographic variation in observed diversity of mammals, but within these patterns there are finer grained anomalies in distribution that result in areas with extremely high diversity, the so-called hot spots. Across all species of terrestrial vertebrates, 35% of all species are confined to a total of 1.4% of the Earth's land surface. Almost by definition, this includes a large proportion of geographic endemics, and not surprisingly, such hot spots tend to be much more common in the tropics than in temperate areas for reasons obvious from the above discussion of geographical patterns of diversity. This pattern has strong implications for priority setting in conservation of mammals in the tropics, with a greater bang for the buck (as measured by species protected for dollar expended) if conservation investments are focused in these hot spot areas.

The geographical and geological precursors that lead to high levels of species endemism are not well understood.

Despite the radical difference in life histories and evolutionary histories, patterns of endemism frequently are highly congruent across taxa, indicating necessary and sufficient conditions are probably common to the evolution of endemism in mammals and other taxa. Indeed, in Africa and its associated islands, endemism of plants and animals converges, with the hottest of the hot spots for all taxa being found in places like Madagascar, the Karoo, the Cape Province of South Africa, and the Ethiopian Highlands.

The diversification of a small number of families on islands is probably as much due to vicariant or random arrival of animals on the island as it is to any set of geological or climatic conditions. The diverse lemur fauna of Madagascar and the rapid radiation of marsupials on the Australian continent owe as much to isolation as they do to anything else. The rapid, and astonishing, diversification of cichlid fishes in the rift lakes of Africa or the convergent pattern seen in the fish genus *Semionotus* in the Jurassic rift lakes of the East Coast of North America also shows the potential for rapid evolution of endemics in habitat 'islands' within a larger continental setting.

However, isolation *per se* does not explain the evolution of endemism on larger continents, where connections to other source populations of mammals have come and gone over the epochs. Africa, unlike other continents, has retained a relatively stable location on the globe through the past 300 million years. Such stability, relative to the drift of other plates, has provided a relatively constant set of ecological conditions as associated with latitudinal changes. Superimposed on this stability, however, have been the making and breaking of connections to Asia, repeated geological upheavals associated with the repeated formation of an African rift, and a cycle of drier periods that led to expansion and contraction of the extent of the central African forests.

Within this geologically unstable environment, there have been areas of remarkable stability, areas that have been consistent in their patterns of temperature and rainfall, whether hot and dry or hot and wet. This climatic stability has led to the evolution of endemic mammals in places as diverse as the Ethiopian Highlands, the forests of the Congo basin (former Zaire), and the Usambara Mountains (although this area is better known for its avian and floristic endemism).

Endemic hot spots appear to be at greater risk than equivalent areas of similar vegetation type. In tropical forests, for instance, in hot spots, only 12% of the original vegetation persists, whereas 50% of all tropical forests still stand. Furthermore, studies have shown a general pattern of increasing threat with endemism, and that this pattern holds for mammals. This suggests that hot spots are an order of magnitude more threatened than the average tropical forest. One explanation for this ties into the evolutionary explanation for hot spots. Many of the same patterns of geography and climatic stability that lead to the evolution of hot spots are also those that lead to the settlement and cultural evolution of humans. Hence, convergent patterns of human cultural diversification and biotic diversification lead to a situation in which people and hot spots are in closer proximity, competing for the same resources and leading to greater conflict than would be expected if species and people were randomly distributed.

New Discoveries and Descriptions

Mammals may be exceptionally well described, as compared with other taxa, but this does not mean that the taxonomy of Mammalia is either complete, or stagnant. In the decade 1992–2003, more than 340 new mammal species were described, with many of these being the result of taxonomic revision. These are not minor revisions, with 28 of these species belonging to new Genera, and one of them a new, monotypic family. Increasingly sophisticated molecular tools, as well as a better understanding of processes of phylogenetic divergence, suggest that this pattern of increasing mammalian diversity will continue, and perhaps in the near term accelerate, as Families are revised and new molecular tools applied. Most of these species are found in the species-rich tropics, and appear to have a restricted range size.

Patterns of Discovery

The discovery of a new mammal, even a large mammal, is not such an unusual event. In the past 60 years, more than 2 dozen species of large mammals have been described and several others are known but await formal description. Mammals in general follow a rate of about 25 new descriptions per year. Consideration of the pattern of description of new species of mammals shows that the curve is more or less bell shaped (Figure 3), with the peak of activity in describing mammals coming early in the twentieth century. While new mammals continue to be discovered each year, the rate at which these discoveries have occurred has not changed significantly in recent decades.

If finding new species is not a particularly rare event, can we predict how many species will eventually be discovered? Recent analysis of the discovery and description of large

(> 2 m) open-water marine mammals suggests perhaps that 47 species await formal scientific description, that we should continue finding species at a rate of one new species every 5 years, and that we are most likely to find new cetaceans. Given the long and intensive history of commercial whaling, such a finding is surprising.

New species can be named in one of several ways. In some cases, specimens collected many decades earlier were neither properly examined nor adequately described. Hence, when a systematist revises a taxon, 'new' species may be found sitting in a museum drawer. Similarly, new forms of evidence from field, laboratory, or genetic studies may force a revision of a species group. Molecular genetics has played a large role in this field, forcing scientists to reassess previously assigned taxonomic names. Finally, previously unknown forms may be found in nature.

The Annamites: The Last Frontier for Large Mammals

The Annamite mountain range, which forms the border between the Lao People's Democratic Republic and Vietnam, has yielded a large number of discoveries of new species and re-discoveries of previously described species of large mammals in the past decade. The Vietnamese warty pig, *Sus bucculentus*, long thought to be extinct, was found in a food market in Laos in the early 1990s. The field has been particularly rich for discovery of barking deer, primitive deer found throughout the tropics of southern Asia and Southeast Asia. In 1994, the giant muntjac was discovered in the forests of the Annamites. Large in size and with unusual antlers, the species was thought sufficiently morphologically distinct to deserve its own genus, *Megamuntiacus*. DNA analysis suggested that the species belongs with other muntjacs in the genus *Muntiacus* (*Muntiacus vuquangensis*) and not in a genus of its own.

Figure 3 The number of new species described (left-hand scale, histogram) and cumulative number of mammal species (right-hand scale, line). Reproduced from Wilson DE and Reeder DM (1999) *Mammal Species of the World*, 2nd edn. Washington, DC: Smithsonian Institution Press, with permission from Nature.

Two further Annamite *Muntiacus* species have been found, one a new species from Quang Nam Province, Vietnam (*Muntiacus truongsongensis*), and another from the Lao side of the border, a rediscovery of Roosevelt's muntjac, *Muntiacus rooseveltorum*. In neighboring Myanmar (Burma), a 1997 expedition to the far north of the country, an area not visited by scientists since the 1930s, yielded discovery of the world's smallest deer, another species of muntjac, the leaf deer (*Muntiacus putaoensis*).

The Annamites have also been the source of three discoveries that have both puzzled and captivated scientists. The first is the saola, or *Pseudoryx nghetinhensis*. The species, which weighs approximately 100 kg, derives both its scientific name and Lao common name from the shape of its horns: long and arched, the species' horns resemble both the Africa oryx and the arc of a lyre-like Lao musical instrument. Initially found only in the Vu Quang forest reserve, Vietnam, the species is now known to range widely at higher altitudes in the Annamites. Most closely related to bovids, the saola is clearly unusual and represents a deep branch in the phylogeny of the bovids.

Another, perhaps even more curious, Annamite discovery was that of a new rabbit species (*Nesolagus timminsii*). The rabbit, which has distinct, dark brown stripes running down both its face and back, a reddish rump, and short ears, was first identified in a food market in Ben Lak, Laos, but since has been photographed in Vietnam. The rabbit's closest relative is a critically endangered species found in Sumatra, about a thousand miles away (*Nesolagus netscheri*). Despite extreme morphological similarity, genetic data suggest that the two species may have diverged about 8 million years ago. The two are so divergent genetically that it was debated as to whether the new (as yet unnamed) species should be placed in its own genus.

If these discoveries were not expected, a species described in 2005, the Laotian Rock Rat (*Laonastes aenigmamus*) is perhaps even more remarkable in being not just a species new to science, or Genera, but an entirely new Family, Laonestidae one of only three Families added to the Mammalia since 1900.

Cryptic Species, Phylogeography, and Evolutionary Significant Units (ESU)

New discoveries do not require going to the ends of the earth. The pipistrelle (*Pipistrellus pipistrellus*) is one of the most common bats in Europe, and one of the best studied. In the British Isles it was found that the bat used two frequencies to echolocate, which led scientists to classify these populations as either the 45- or 55-kHz phonic type. Because roosts consisted of bats of a single phonic type, to these scientists it was suggested that the phonic types represented sympatric, but distinct, species. Because of their morphological similarity, they are called cryptic species. Two recent studies have provided further evidence that these two phonic types are, indeed, good species. The two show relatively good separation of diet: whereas both eat mostly the dipteran suborder Nematocera, the dominant prey groups for the 45-kHz phonic type were in the families Psychodidae, Anisopodidae, and Muscidae, while

the families Chironomidae and Ceratopogonidae were the main prey groups of bats of the 55-kHz phonic type. Studies of the cytochrome b gene also showed unambiguously that the two phonic types are distinct species. That such cryptic species can be found in such a well-studied group suggests that further genetic studies of mammalian phylogenies will yield some surprises.

Molecular genetics is a powerful tool for disentangling the relationship between the geographical and morphological history of subspecies within a species group, the study of phylogeography. Because morphological, geographic, and genetic data frequently tell different stories (as in the striped rabbit e.g., above), an understanding and reconciliation of these data are critical to understanding both the evolution and conservation of mammals. The recent study of Australia's largest extant carnivore, the marsupial tiger quoll (*D. maculatus*), is instructive. The quoll occurs on Tasmania and on the mainland in two distinct populations, one in the north and one in the south. Previous to genetic analyses, strong body size and morphological convergence led to the southern and Tasmanian populations being grouped as one subspecies (*D. m. maculatus*), whereas the northern population was classified as a separate subspecies (*D. m. gracilis*).

Genetic evidence suggests, however, that despite their size differences, which may be as much as 50%, the two mainland populations are more closely related to one another, while the Tasmanian population is genetically divergent. Why does this matter? If the two mainland populations constitute one ESU while the Tasmanian population constitutes a different ESU, then one management solution would be to manage the mainland and island populations separately. This would ease management concerns as the northern population is classified as endangered, whereas the southern population is relatively more common. Yet, it is likely that if a female northern quoll were placed in a breeding center with a southern male, because of their great size difference, the male would view the female as dinner, not as a potential mate. Similarly, translocation of southern quolls to the north to augment that population could be disastrous. Hence, although phylogeography suggests one management regime, a more complex solution, with each population managed separately, is recommended.

Current Extinction Crisis

How Many Species Have Gone Extinct?

The current rate of extinction of mammals is, by any measure, frightening. In the past 500 years, approximately 88 species of mammals are thought to have gone extinct. This represents approximately 1.9% of the extant species of mammals. Using the 'background' or natural rate of extinction derived from an examination of the fossil record, one would have expected at most one species of mammal to have gone extinct in the same time period. This accelerated rate of extinction can be ascribed, directly or indirectly, to a single cause: humans. While determining what factor is ultimately (as opposed to proximately) involved in a species extinction, habitat loss, introduction of exotic species (including zoonotic diseases), and

overharvesting all have contributed to the high historic rates of mammalian extinction.

One would think that assessing the rate of extinction in such a well-studied group as mammals would be relatively easy. Yet, despite relatively good taxonomy and detailed study of the question, there remains considerable debate among mammalogists and conservationists about the number, the precise identity, and the timing of disappearance of those species that may have gone extinct in historical times. In the 1990s, two efforts to categorize historical extinctions came up with approximately the same number of species going extinct: 85 by one estimate and 88 by another. What is disconcerting, however, is that the two lists contain only 57 species in common, resulting in, overall, 116 different species being listed by one or another of these studies. This suggests that, even among experts, there is some debate about what actually constitutes an extinction.

How much does this matter when assessing patterns of modern loss of mammalian species? On the one hand, documented extinction rates are so far over background rates that definitive listing will not change the implications for conservation of mammals. On the other hand, such lists are playing an increasingly important role both in setting priorities for conservation (the process of keeping species off the list) and in public debate, and an accurate, defensible list is essential.

A clear ability to agree on what is meant by extinction is critical both to conservation planning and to conservation science. While all differences in lists of extinct species need to be reconciled, much can be learned by analyzing why one set of authors excludes species that other authors list as extinct (Table 4). The reason(s) why authors disagree can tell us much about the source of such errors, or differences of opinion, and also help us focus our efforts more clearly on those species where changes in status affect conservation action.

Most lists examine the extinction of species over a particular time frame. For instance, one might examine mammalian extinctions since the beginning of the age of exploration starting in 1500. The first question one must ask is, did the species in question really exist at any time during the past 500 years, or was extinction during this time inferred incorrectly either through data in the literature or from misplaced stratigraphy of sub-fossil material? In Table 5, clearly a plurality of the 76 species excluded were in this category. There is no dispute whether or not these 31 species went extinct, rather just a question of whether their extinction predated the period under study. While inclusion or exclusion of these species will change the calculation of rates of extinction, such changes have little practical applications to conservation.

Similarly, removing or adding a species from a list for reasons of taxonomic uncertainty or taxonomic revision does not manifestly change conservation status of a species. Take for instance the quagga. Distinct from other zebras, with only vestigial stripes, the quagga, *Equus quagga*, was initially thought to be a distinct species of zebra extirpated from the southern tip of Africa at the turn of the twentieth century. Molecular analysis of museum specimens showed unambiguously that the quagga was a subspecies of the common zebra, *Equus burchelli* – one less extinct species, to be sure – but such revision does not change the way we manage the existing

Table 4 A review of species not accepted as “Extinct”

Species not known to exist in past 500 years	31
Species extant as another taxa	18

populations of *E. burchelli*. Similarly, if two extinct species are found to be synonymous, as in the case of Johnson's hutia (*Plagiodontia ipaneum*) and *Plagiodontia veloz* (no common name), management plans remain unaffected.

When a species thought to be extinct is determined to still be extant, more likely than not the size and status of the extant population will be either totally unknown or known to be critically endangered. Hence, transition from extinct to extant, unlike other categories, has important conservation implications. In Table 4, such cases represent about one-quarter of those species listed. Such a transition should be a red flag indicating that further study, and conservation action, are likely needed.

Patterns of Modern Mammalian Extinctions

Although the rate of extinction is extremely higher than the expected background rate of extinction, the time frame over which historical extinctions have occurred is so short that it is often difficult to discern patterns in data collected on mammalian extinction. Nonetheless, both taxonomic and geographical patterns do emerge, both of which may be informative if we try to project future patterns of extinction in mammals.

Perhaps the most striking pattern seen when one examines data on historical extinctions of mammals relates to the geographic distribution of extinct species. In the past 500 years, the great majority of extinctions have been on islands, and

within island groups, the Caribbean islands have suffered the most extreme loss, accounting for nearly 40% of all recorded extinctions (Table 5). Mammalian extinctions are, in this case, no different from those of other well-studied taxa, with more than 90% of modern avian extinctions and 89% of modern molluscan extinctions also occurring on islands. In recent times, continental extinctions have, for the most part, been rather rare, and nearly all continental extinctions have been on the continent of Australia.

A recent sophisticated statistical analysis of the correlates of mammalian extinction in the Holocene (Turvey and Fritz, 2011, p.0955) has shown that although there are correlates of extinction, these have changed more than the past 12,000 years. Extinctions of mammals have been greatest on islands, or on continental areas with long histories of human inhabitation, and relative human domination of ecosystems. Particularly on continents, larger mammals are more susceptible to extinction; as a result of an interaction between human dominance, and body size, the newest waves of extinctions appear to be concentrated in South Asia and the New World, particularly the formerly remote regions of the Amazon. Finally, the threats to mammals appear to have changed over time, with introduced species (of particular importance to island populations) and overexploitation being supplanted by widespread habitat loss and fragmentation as the current most significant threat to mammals. Clearly, the overlay of climate change, and potentially radical shifts in community structure, will amplify and likely become even more important than current threats.

One of the most striking set of extinctions is in the Insectivora, where an entire family (Nesophontidae, the Antillean island shrews) has gone extinct. Eleven percent of all mammalian extinctions recorded in the Modern era have occurred in this family. Insectivora, as an order, appears to have a greater propensity to extinction, with 11 species having gone extinct, representing 2.5% of the ± 450 described species of Insectivora. This is approximately 30% above the overall rate of 1.9% for mammals.

Other orders that have overrepresentation in recent extinctions include two eutherian orders, the most diverse being Rodentia (52% of all extinctions, 44% of described mammals). Similarly, among therian mammals, the most diverse order, Diprodontia, with 117 species, which includes possums, cuscuses, wombats, and the koala, shows overrepresentation in the extinction table (6.8% of extinctions, 2.5% of all mammalian species) as does one of the least diverse, the Perameldia, or bandicoots (3.4%/0.45%).

In contrast, whereas nine species of the order Chiroptera have gone extinct, representing 10% of the known modern extinctions, bats represent nearly 20% of the extant modern mammalian fauna; hence, one could argue bat extinctions have been underrepresented in recent times. Similar arguments could be made for both carnivores (2.2% of extinctions, 5.8% of species) and primates (3.4% of extinctions, 5.1% of species).

Projecting Future Extinctions

Compiling lists of recently extinct species and studying current extinctions tells us something of the recent history of changes

in mammalian biodiversity. The strength of such lists is that they are an assessment of the global patterns of extinction and tell us something about the persistence of a species, family, order, or size class. To better understand the immediate future of mammalian extinctions (perhaps the next 200 years) rather than reflect on what has gone extinct, there is greater value in examining which species, families, and orders are under threat and discussing how threats will lead to decline, and ultimately to extinction. Unnervingly, most of the newly described species have been found in increasingly threatened tropical forests in Asia and Latin America, have narrow geographic distributions, and hence are ever more likely to face extinction. These processes are more fully discussed elsewhere in this encyclopedia, as are patterns for particular orders of mammals.

For mammals overall, however, patterns of threat do not correlate well with patterns of recent extinction. A recent assessment of threatened species by the World Conservation Union (IUCN) suggests that 25% of extant mammal species are threatened with extinction. Some of the groups that are overrepresented in analyses of recent extinctions are prominent in the list of threatened species: rodents are somewhat underrepresented, with 'only' 17% of the species in the order threatened with extinction; insectivores, however, look likely to dominate the lists of extinct species in centuries to come, with 36% of the species in this taxon threatened. What is more interesting is that some orders that have shown relatively low rates of extinction such as carnivores and primates have high proportions of their taxa threatened. In carnivores nearly 26% of all species are under threat, whereas nearly half the primates, 46%, may go extinct in the next century.

Analysis of the extinction of subspecies or populations of animals gives some insight into what is generating this pattern. Among both carnivores and primates, rare species have been subject to increasing threats from habitat loss and fragmentation, isolating endemics in smaller and smaller patches. But wide-ranging species are also showing promise for future extinction through similar processes acting at larger scales. The spotted hyena, although still abundant and occurring at relatively high densities for a large carnivore, requires a matrix of resources that are widely dispersed across a landscape. Combined with a relatively low level of dispersal, habitat fragmentation and isolation suggest the species will come under increasing threat. The African wild dog still has a nearly continental distribution, but most populations are small (fewer than 100 individuals) and increasingly isolated. Threats to the species amplify one another: habitat loss and fragmentation, loss of prey, disease introduced by domestic companion animals, active hunting, and road kills all contribute to mortality. The decline of the species in West Africa, where populations became isolated and then went extinct one by one, like candles being snuffed, is probably indicative of patterns that are evolving in central and East Africa. Increasingly, although the species is still extant, and will remain so for decades in southern Africa, it is being lost as a component of the great majority of ecosystems in which it once lived.

While extremely valuable both for planning and for developing an understanding of which species are most likely to go extinct, lists of extinct or threatened mammals only address the concern of evolutionary extinction, the ultimate loss of a species. Increasingly, scientists who study mammals, and

lobby for the preservation of mammalian diversity in particular and biodiversity more widely, will have to address issues related to the local, regional, and global ecological consequences of a species' march toward extinction.

Glossary

Conservation efforts Any action that aims to reduce the probability of extinction of a taxon over a specified time period.

Ex situ conservation Conservation activities that involve individuals held outside their native habitats (e.g., in zoos or seed banks).

In situ conservation Activities which aim to conserve wild populations in their native habitats.

Mammal Member of the order Mammalia. A species that provides milk for its young and has fur. They typically (but not exclusively) bear live young.

Persecution Deliberate killing of animals perceived to be a nuisance.

Range state A country in which an animal is found.

Sustainable use Exploitation of wildlife in a manner that avoids depletion of the resource (e.g., limited hunting, ecotourism).

Terrestrial A species that lives on land (as opposed to marine or fresh water) for the majority of its life cycle.

Conservation efforts for mammals must start with a consideration of the particular threats that face these species. Mammals are a disparate group, but similarities in their conservation needs can be discerned, particularly when considering large mammals. Large-bodied species tend to be vulnerable to extinction both because of their biology and their interactions with humans. They typically need large areas for survival and to be relatively slow growing, making their populations less resilient. They also tend to be more likely to be killed by humans for their meat, trophies, or because they are a danger or a nuisance. Because of these varied threats, conservation efforts for mammals are broader than for some other taxa; they encompass both habitat protection and direct protection. Conservation efforts for mammals are also noteworthy because these species are often treated as flagships for the rest of biodiversity conservation, sometimes at the expense of other species. This makes mammals important more broadly for conservation policy.

Introduction

In discussing conservation efforts for mammals, we first need to identify what is particular about their conservation needs. It is hard to generalize about such a broad range of species, from bats and mice through antelopes, manatees, and lynx to elephants and whales, but there are some common characteristics that predispose mammals to threat, at least among larger-bodied species. These characteristics relate both to natural history and to human attitudes.

Large mammals have high energetic demands. They grow slowly, range widely, and occur at low population densities.

Together these linked characteristics mean that large mammals are vulnerable. Their population dynamics may be less resilient than those of other species, since they cannot bounce back quickly from population declines. Furthermore, they may be more affected by habitat loss than are other species, because they often have large home ranges, and require larger areas of habitat.

The natural history of mammals is not the only feature that predisposes them to vulnerability – large mammals are often under threat because humans deem them to be worth killing. Being large bodied, most are valuable for meat; those that have trophies such as horns, tusks, or furs can be extremely valuable. The economic value of mammals makes them vulnerable to overexploitation, but it can also be used as a tool for their sustainable use, and ultimately, their conservation. Large mammals can also be prone to human persecution because they represent a threat both to humans themselves and to their livelihoods; they kill livestock, or compete for land and resources. However, some mammals are charismatic, and some are considered iconic (e.g., tigers, elephants, and pandas), which means that people may be prepared to invest heavily in their conservation, and that they can generate substantial sums for conservation through tourism. For this reason, large mammals often act as flagships for the conservation of their ecosystems.

Large mammals can have a significant impact on their environments. This creates an intimate association between the conservation of terrestrial mammals and the conservation of other species in their ecosystems; conservation efforts targeted toward mammals might, therefore, have added value over and above the individual species being conserved. Some mammals have a profound impact on the ecosystems they

inhabit. For example, the reintroduction of wolves to Yellowstone National Park triggered a trophic cascade, in which wolf presence affected elk behavior, and through them the vegetation of the Park, increasing the amount of woody vegetation such as aspen and cottonwood. The reintroduction also reduced populations of the coyote, a smaller predator, which the wolves killed. Scavengers such as grizzly bears benefited from wolves, scavenging at wolf kills. It is difficult to predict in advance the outcome of the interacting effects of removing, or reintroducing, large mammals on their environment, but it is clear that these effects can be profound (Smith *et al.*, 2003).

In this article, we will first discuss in general terms some of the threats facing mammals, and which species are particularly vulnerable to these threats. We will then discuss conservation measures that have been used to address some of the threats. Finally, we will use three in-depth case studies to exemplify a range of species conservation efforts implemented in response to an array of threats operating from localized up to regional scales. We conclude by placing mammal conservation into the broader context of international conservation efforts.

Threats to Mammals

Like other taxa, many terrestrial mammals are at risk from habitat loss. As people become more numerous, they modify their surroundings in a variety of ways; this process creates new environments hostile to many wild species. Direct conversion of natural habitat threatens the high proportion of mammal species that cannot survive in farmed or urban environments. Many terrestrial mammals' large body size and high energy requirements make them particularly sensitive to human activities. Freshwater mammals such as river dolphins are also highly susceptible to habitat degradation and pollution.

Direct killing by people is a serious threat, which perhaps affects mammals more than other groups (with the possible exception of commercial fish species). Some forms of killing are due to exploitation. Subsistence hunting of deer, antelopes, and many primate species can cause population declines, as can commercial hunting to fuel local and international trade. The bushmeat trade (trade in meat from wildlife for local consumption) is predominately based on mammal species; the annual offtake for this trade has been estimated to be 2.2 million tons of meat a year in the Congo basin alone (Fa *et al.*, 2003). There is a strong interaction between hunting and habitat loss; as an area becomes more accessible through the creation of logging roads, for example, hunting rates increase. The extinction of the Yangtze river dolphin has been attributed to a combination of targeted hunting, direct mortality from entanglement in nets, disturbance, collisions with boats, and habitat degradation. Likewise, the presumed extinction of the kouprey, a wild ox, has been linked to intense hunting of large mammals in Indochina. Hunting for the international trade has caused some of the most serious and well-publicized species declines and includes hunting of elephants to make ivory carvings, spotted cats to make fur coats and whales for oil, meat, and baleen. Of particular concern, in recent years, has been the heavy demand for animal body parts used in traditional Asian medicines; this

has caused declines of tigers (for their bones and other body parts), rhinoceros (for their horn), and bears (for their gallbladders).

Not all killing of mammals by people constitutes exploitation; several species, especially the large carnivores, have suffered serious declines through persecution. Large-bodied species such as elephants and bears are a risk to human life and are rarely tolerated in areas with high human densities. Much of the problem with human–elephant relationships in recent years is concerned with the fact that elephants are dangerous neighbors. Elephants can flatten a crop in minutes and are responsible for many human injuries and fatalities each year. Likewise, large carnivores are feared as a threat to both people and livestock, and have been the victims of organized eradication campaigns that saw, for example, the extirpation of wolves from most of the United States, and African wild dogs across much of Africa, in the first half of the twentieth century. Humans may also cause inadvertent declines through exploitation or control of relatively common species. Traps set to catch rabbits are a serious threat to endangered Iberian lynx, which are accidentally captured and killed. Extermination campaigns for prairie dogs inadvertently caused the collapse and near-extinction of the black-footed ferret.

Human activities also influence wild mammals' exposure to "natural" threats such as disease and predation. Frequent local extinctions of bighorn sheep in the Western United States, leading to serious species decline, have been largely attributable to infectious diseases contracted through contact with domestic sheep. Small, isolated populations are especially vulnerable to the threat of disease; thus disease may deliver the final *coup de grace* to species already crippled by other factors. Likewise, these populations may be unable to cope with the predation pressures which can be sustained by larger populations. When exotic predators or pathogens are introduced to naive species, the impact can be more severe still. The introduction of red foxes to Australia decimated populations of the smaller marsupial species, and the introduction of rinderpest – a viral disease of Asian cattle – to Africa caused widespread and often irreversible declines of many African ungulates.

The regular updating of the World Conservation Union's (IUCN) Red Lists of threatened species provides an opportunity to analyze the relative importance of different threatening processes. Schipper *et al.* (2008) showed that 25% of mammal species were threatened. Only two other taxonomic groups had then been fully assessed and so are directly comparable, birds (14% threatened) and amphibians (32% threatened). Schipper *et al.* identify six major threat types. For mammals, the top two threat types are habitat loss (37% of the threats) and overexploitation (17%). Other threats, such as introductions (6%) and pollution (4%), are less often serious threats for mammals. Thus any analysis of the threats to mammals and the conservation efforts needed to counteract them is likely to emphasize habitat loss and overexploitation.

Another useful technique for looking at the relationship between threat and extinction risk compares the characteristics of populations that have become extinct with those that survive. These studies have shown that vulnerability correlates with species' natural history, but that this interacts with

anthropogenic factors. For example, carnivores with large home ranges frequently travel beyond the borders of protected areas, where they come into contact with people. Such contact is often fatal, with the result that wide-ranging species require larger parks and reserves for effective protection (Woodroffe and Ginsberg, 1998). The direct and indirect effects of human activity on mammals lead to general associations between high human population density and local extinction of mammal populations. Elephants, primates, and carnivores all demonstrate such associations. This probably reflects complex interactions between direct killing of mammals by people, destruction of mammals' habitat by people, or, on the small scale, simple avoidance of people by mammals. Price and Gittleman (2007) showed that artiodactyls (even-toed ungulates) are more likely to be threatened if they live in areas of high poverty, and that if a species is also hunted, then slower-growing species are more likely to be threatened. The effect of living in poor areas is probably related to the degree of human use of wildlife habitat and habitat clearance that is going on, whereas the effect of the species' biology is probably because slow-growing species are less resilient to high levels of hunting.

In summary, individual species may be threatened by a number of different factors, so that the type of conservation effort needed to counteract these threats can also vary widely between species. However, it is possible to discern some broad patterns that can help to identify species that may be at particular risk of extinction. These patterns relate both to the biology of the species and to the level and type of human pressure on the species and its habitat.

Types of Conservation Effort

The threats described above demand a variety of conservation measures. We discuss these measures briefly, giving more detailed evaluations of their costs and benefits in the case studies.

Legal protection of areas is the most traditional form of conservation; this approach, if effectively enforced, has the advantage of protecting habitats, as well as particular species, against a multitude of threats associated with human activities. While reserves are often targeted at a particular species, and even named as such (e.g., Addo Elephant Park, Gemsbok National Park), well-planned reserves can protect multiple species, habitats, and landscapes. Large mammals are often used as "flagships" to promote such reserves (e.g., India's Project Tiger). Craigie *et al.* (2010) analyzed mammal population trends in African protected areas over the period 1970–2005, and showed an average 59% decline in species' population sizes within protected areas, which suggests that overall, protected areas are not enough to conserve Africa's mammal populations. However, they uncovered major regional differences; in southern Africa populations were generally stable, while severe declines were recorded in West Africa. This suggests that a better understanding of what makes protected areas successful in some areas and not in others could markedly improve conservation effectiveness.

Legal protection of species or populations may also be used as a conservation measure. For example, stringent legislation in

the United Kingdom protects the European badger from killing and disturbance. International treaties have effectively protected many cetacean species from intense overhunting, and led to population increases in previously highly threatened species such as the bowhead whale (George *et al.*, 2004). Difficulties of enforcement mean that such legislation may have limited value as a conservation tool in countries without effective governance, however; for example, a wide range of mammals is still openly traded for meat in the Democratic Republic of Congo despite having full legal protection (Rowcliffe *et al.*, 2004). Species threatened by exploitation may be protected by *legislation governing trade* rather than preventing killing. For example, it is not illegal to kill leopards in some countries, such as the Gambia, but international trade in their skins is prohibited from or to member countries of the Convention on International Trade in Endangered Species (CITES).

Problems surrounding the enforcement – and ethics – of legislation prohibiting the exploitation of wild populations or use of protected areas have led to initiatives aimed at conservation through *sustainable use*. The rationale behind such initiatives is that sustainable use should ensure that local people value and protect natural resources, if the benefits accrue to local communities. Like the establishment of reserves, this approach has attracted controversy; the array of political, legislative, and logistical concerns that it entails is different from, but no less complex than, that surrounding more traditional legal protection. At the international level, sustainable use and equitable sharing of the benefits from biodiversity are at the heart of the Convention on Biological Diversity.

Threatened populations may also be protected through direct management, particularly when the population has become very small and unlikely to survive in the wild without intervention. *Habitat management* involves measures such as provision of waterholes or den sites, or control of predators (both native and invasive). *Population management* describes a variety of interventions such as vaccination against infectious diseases and supplementation from other populations, wild or captive. Species conservation may also involve reestablishment of extinct populations through reintroduction of captive-bred or wild-caught mammals. Such measures have been important in the recovery of some endangered species (e.g., golden lion tamarins and red wolves), as well as for the reestablishment of populations of species that remain widespread but have suffered local extinctions (e.g., gray wolves).

Finally, the conservation of some endangered species may benefit from *captive breeding*, maintaining a population in captivity that may or may not be intended for release into the wild. Such efforts have proven valuable for critically endangered species reduced to their last few individuals (e.g., Arabian oryx, black-footed ferret, and island fox), in which managed breeding can minimize the loss of genetic variation. However, captive breeding is a choice of last resort, as it can lead to the loss of wild behaviors. Animals that are habituated to people are particularly vulnerable to persecution or exploitation once reintroduced. Przewalski's horse, however, provides an example to show that all is not lost when species are reduced just to a few individuals in captivity. In this case, the individuals were not even genetically pure, with their gene pool having been contaminated by domestic horses.

However, the species has now been reintroduced to the wild and is displaying natural behavior (Boyd and Bandi, 2002).

Case Studies

Mammals cover such a range of habitats, biology, and interactions with humans that it is very difficult, in three short case studies, to give a flavor of the status and conservation efforts for all mammal species. However, we have chosen three case studies that exemplify many of the issues, covering a variety of species and continents; the saiga antelope in Central Asia, hutias and solenodons (small mammals found on the islands of the Caribbean), and the cheetah and wild dog across their range in Africa. Major omissions include marine mammals and the bats, but we hope that the insights from our case studies shed light on some of the issues facing other mammals as well.

Saiga Antelopes

The saiga antelope (*Saiga tatarica*) has had a torrid time in the past two decades. Buffeted by geopolitical forces – the breakup of the Soviet Union and high Chinese demand for its horn – its population crashed in the first half of the 2000s, leading to the dramatic uplisting of the species on the IUCN Red List from Near-threatened to Critically Endangered, the highest threat level, in one step. Since the mid-2000s, however, substantial conservation efforts have been mobilized on every scale, and the species now represents a conservation success story, despite the continued threats which it faces.

Background

The saiga antelope (Figure 1) is a nomadic herding species found in the semiarid rangelands of Kazakhstan, Russia, and Mongolia (Figure 2). It has two subspecies, *S. t. tatarica* and *Saiga t. mongolica*; the latter is found only in Mongolia. The Kazakhstan populations of the species migrate over very long

Figure 1 Picture of a saiga antelope. The saiga is about the size of a domestic goat, with a sandy-colored upper body and a creamy underside. This picture shows an adult male, which has horns of an unusual translucent amber color. The species' most striking feature is a protuberant nose, which swells further in rutting males. Picture by Navinder Singh.

distances, up to 1000 km, moving between winter pastures in southern desert regions and summer pastures in the steppe zones of the north. This enables them to track green vegetation and to escape from the heaviest snows of the winter (Bekenov *et al.*, 1998). Within its summer and winter ranges, the species is nomadic, a response to the harsh climatic conditions of the continental ecosystem in which it lives, allowing herds to move rapidly away from areas where there is bad weather or where other threats exist.

The species stops to give birth in huge aggregations in the spring, which is thought to be a predator-swamping adaptation, protecting the calves from wolf predation. Females twin consistently once they reach maturity. This is unusual among ungulates and means that the population can increase very rapidly in good years, allowing populations to recover quickly from overhunting, harsh winters or disease outbreaks. It has a harem breeding system, in which each adult male controls and mates with a group of 12–30 adult females, making the population resilient to male-biased hunting, which is important because only adult males bear horns, which are highly prized in Chinese medicine. Overall, therefore, the saiga antelope is a resilient species that is capable of withstanding relatively heavy hunting pressure and of recovering quickly from episodes of high mortality.

The saiga has been hunted for its meat, horns and hide since prehistoric times. In the eighteenth and nineteenth centuries, it was hunted in large numbers by the St Petersburg Imperial court. By the early twentieth century, hunting had reduced it to near-extinction. Horn prices were very high, with horns exported for use in Chinese medicine. During the Soviet period, up to the mid-1990s, the population was well managed, with legal protection and regulated commercial hunting, and grew to relative stability. However, the situation changed dramatically with the breakup of the Soviet Union. Rural poverty and unemployment, combined with the opening of the border with China and high prices for horn, as well as a collapse in law enforcement and management, led to massive poaching of the species, causing a 95% population decline in just 10 years and triggering its listing as Critically Endangered on the IUCN Red List in 2001 (Figure 3). Since conservation efforts started, around 2003/2004, the global population of the species has started to rise steadily, although it is still well below its 1980s level.

Threats

The major threat that has affected populations of *S. t. tatarica* over the past 20 years has been massive illegal hunting for both horns to supply international markets and meat for local consumption, causing the population decline shown in Figure 3. However, limiting factors in the past have included habitat degradation from overgrazing, infrastructure development, particularly canals in which large numbers drowned, and epidemics of disease, probably contracted from the livestock that share the saiga's range (Bekenov *et al.*, 1998). It is important not to forget these other factors when focusing on the main threat of poaching, as was demonstrated in May 2010, when 12,000 saigas were found dead in the Ural population after several years without any sign of disease. The dead saigas were adult females which had just given birth, and although the ultimate cause of death is still not clear, this was

Figure 2 Map of the range area of the saiga antelope, from Milner-Gulland *et al.* (2001). There are four distinct populations of *Saiga t. tatarica*, shown as stippled areas. Three of these are in Kazakhstan (2: Ural, 3: Ustiurt, 4: Betpak dala), the fourth in the pre-Caspian area of Russia (1). The other subspecies, *Saiga t. mongolica*, has only a few thousand individuals and is found in Mongolia (5).

Figure 3 The population trajectory of the saiga antelope in Kazakhstan, 1980–2010. Data are from the Institute of Zoology, Kazakhstan, and are predominately from aerial censuses. In the 1980s, the population was heavily hunted, and population size also fluctuated due to environmental changes from year to year.

a warning that disease is a potentially potent threat; this single week of mortality killed one-third of the estimated Ural population. Looming future threats include the effects of climate change on vegetation productivity and temperatures, and development of the extensive steppe regions where the species lives, particularly for gas and mineral extraction.

Conservation Efforts

The fact that the main threat to saigas over the past two decades has been hunting means that engaging with people is the

only way to address this urgent threat. Conservation efforts have therefore focused on strengthening law enforcement, building public awareness of the problem and changing attitudes among hunters and consumers, locally and in China. A few projects have also offered alternative livelihood opportunities to local people, but these have been small-scale and it is hard for a conservation project to counteract the momentum of massive social and economic changes at the national and regional levels. Law enforcement has generally been carried out by governments, with financial and logistical support from large international NGOs, whereas the public engagement activities have been carried out by in-country conservationists in collaboration with smaller, more species-specific NGOs.

The saiga antelope is a good example of how international treaties can guide and integrate conservation efforts toward effective action. In 2006, saiga conservationists from government, NGOs and international bodies met under the Convention on Migratory Species (CMS) to sign a Memorandum of Understanding (MOU) on saiga conservation, and to endorse a Medium Term International Work Programme, which prioritizes conservation actions according to their urgency and their importance for preventing extinction, both for the species as a whole and for individual populations. In 2010, the parties met again to evaluate progress and to agree a new work programme for the next 5 years. Often international meetings can be “talking shops” with little relevance to on-the-ground conservation, but the evidence suggests that the CMS saiga MOU has been very effective in channeling conservation activities into agreed high priority areas, holding all those who

carry out saiga conservation to account, and promoting communication, cooperation, and transparency (CMS, 2010).

Conservationists are continuing to work with local people in the saiga's range states, and to support law enforcement activities. However, the emphasis is shifting, and it is now important to evaluate the lessons learnt from the successes and failures of conservation interventions since 2003, for example, whether local people are actually changing their attitudes in response to public awareness campaigns (Howe *et al.*, 2011). Looking to the future, Kazakhstan is developing a landscape-scale system of protected and multiple-use areas for one of its saiga populations, in order to enable people and saigas to coexist in the steppe ecosystem sustainably, in the face of development pressures and climate change. There is also an increasing emphasis on engaging with China, both at the governmental level and through NGOs and consumer groups, toward a long-term solution to meeting the demand for saiga horn, which otherwise will continue to act as an irresistible force incentivising poaching.

Urgent conservation intervention and a lot of publicity for the saiga's plight were needed in order to ensure that the saiga did not crash to extinction as a result of the collapse of the Soviet Union. Relatively small-scale conservation interventions by dedicated individuals and organizations on the ground were able to support the species through the dark times; now that the range states' circumstances are more stable and they are keen to conserve their biodiversity, it is possible to plan for the future of this species.

The Hutias and Solenodons of the Caribbean

Before humans colonized the Caribbean islands some 6000 years ago, a diverse mammalian fauna of around 120 endemic species of primate, rodent, sloth and soricomorph (shrews and relatives) occurred in the region. The vast majority are now extinct, representing perhaps the highest rate of extinction of any mammalian fauna in the past few thousand years. Only 13 species of hutia (a family of the order Rodentia) and two species of solenodon (a family of the order Soricomorpha) survive today on the islands of Hispaniola, Cuba, Jamaica and the Bahamas. They are an extremely threatened group; all but two are globally threatened, with 10 classified as Endangered or Critically Endangered on the IUCN Red List of threatened species.

Background

The only surviving Caribbean soricomorphs are the Hispaniolan solenodon *Solenodon paradoxus* (Figure 4) and the Cuban solenodon *Atopogale cubana*, the last two representatives of the Solenodontidae family. These species have traditionally been placed in the same genus (*Solenodon*), but recent research suggests they diverged from each other around 25 million years ago and should be placed in separate genera. The original solenodon lineage separated from the ancestors of all other living mammals an astonishing 76 million years ago (Roca *et al.*, 2004), before the extinction of the dinosaurs. This ancient mammalian heritage is reflected in some unique characteristics, most notably the solenodon's deep grooves in its incisors, which act as channels to inject venomous saliva

Figure 4 Picture of the Hispaniolan solenodon *Solenodon paradoxus*. Around 1 kg in weight, this adult solenodon resembles a giant shrew with tiny eyes, an elongated and mobile snout and large feet which it uses for digging for invertebrate prey and for burrowing. Picture by Jose Nunez-Mino, Durrell Wildlife Conservation Trust.

into their prey (from the Greek 'solenos' meaning channel or pipe and "don" meaning tooth).

The Hispaniolan solenodon lives in the dry, moist, and pine forests of south-western, central and eastern Dominican Republic and is also known from the Massif de la Hotte in Haiti (Figure 5). Adult Hispaniolan solenodons weigh around 1 kg, and resemble large, well-built shrews with an unusual side-to-side gait. They are mainly nocturnal, sheltering during the day in rock crevices or burrows. Solenodons can often be found in family groups usually made up of between two and four individuals, consisting of an adult pair and one or two offspring. The Cuban solenodon, once widely distributed across Cuba, is now restricted to the eastern end of the island and is extremely hard to find (Figure 6). It has been recorded from the Sierra del Cristal and Alexander Humboldt National Parks (Fa *et al.*, 2002). It shares many characteristics with the Hispaniolan solenodon, but has a darker coat and a striking white mane of fur. Its exact conservation status is not clear and research is urgently needed to better understand its ecology, main threats, and conservation requirements.

The hutias (*Capromyidae*) have an ancient heritage in the Caribbean with the oldest hutia fossils from around 18 million years ago. Many hutia species were lost following Amerindian and European arrival in the Caribbean, including some which have disappeared within the past century. With one species surviving in each of Jamaica (*Geocapromys brownii*), Hispaniola (*Plagiodontia aedium*, Figure 7), and the Bahamas *Geocapromys ingrahami*, most hutia species are found on the main island of Cuba and its surrounding islands (Figures 5 and 6).

The hutias resemble the cavies of mainland South America and vary in size from the rat-sized dwarf hutias (four *Mesocapromys* spp.) to the Desmarest's hutia *Capromys pilorides* which can weigh up to 7 kg. Some species have prehensile tails to facilitate their almost entirely arboreal lifestyle, whilst other species, such as Ingraham's hutia from the Bahamas, are essentially terrestrial. Hutias are herbivorous and can be found in a wide range of habitats, from small and arid coastal cays to high elevation moist forest. In comparison with other rodents,

Figure 5 Map of the geographic ranges of five of the hutias and the Hispaniolan solenodon *Solenodon paradoxus* within the Caribbean. The species' ranges are based on data from the IUCN Red List of Threatened Species (IUCN, 2010).

Figure 6 Map of Cuba, showing the geographic ranges of *Solenodon cubanus* and the eight Cuban hutias. The species' ranges are based on data from the IUCN Red List of Threatened Species (IUCN, 2010).

hutias have very low reproductive rates and typically give birth to one or two young per litter; nevertheless in well protected areas some species can reach very high densities. For example, in Guatanamo Bay in Cuba, Desmarest's hutia, the least threatened of all hutias, reaches densities of more than 1000 animals per square kilometer and its population is now managed to reduce impacts on human infrastructure. With high density populations and good tasting meat, hutias were a very important source of food for Amerindians as they colonized the region, and they are thought to have been kept in semidomestication and transported between islands as a food source. The first meat that Columbus tasted on his arrival to the New World was probably hutia.

Compared to many mammals, the ecology and status of solenodons and hutias is very poorly known. This constrains the prioritization of conservation resources and the design of

targeted species-specific conservation actions and habitat protection measures. At various times during the past century, a number of the solenodon and hutia species have been declared extinct and then periodically "rediscovered" when animals were searched for or opportunistically found dead by scientists. However, three of the species now seem very likely to be extinct, and surveys are urgently needed to confirm their status.

Threats

The earliest major human impact on the Caribbean land mammals was hunting for food by Amerindians, which is likely to have caused a number of species extinctions. Hunting hutia for food has carried on until today, although the extent and population impacts aren't precisely known. In Haiti, there is some evidence that Hispaniolan solenodons are also

Figure 7 Picture of the Hispaniolan hutia *Plagiodontia aedium* showing off its arboreal skills. This species can be found in a range of habitats from mangroves and coastal dry scrubland right up to montane cloud forest. Picture by Jorge Brocca, Sociedad Ornitológica de la Hispaniola.

opportunisticly hunted (Turvey *et al.*, 2008). Other major threats to the solenodons and hutias since European colonization of the Caribbean are habitat loss and predation or competition by invasive mammals. In some countries, habitat loss over the past few centuries has been severe. For example, only 3% of Haiti's forests now remain, which has undoubtedly resulted in massive range contraction of the Hispaniolan solenodon and hutia within this country. Although much more forest remains in the Dominican Republic, Cuba, and Jamaica, it is highly fragmented, isolating small populations of both hutias and solenodons and making them more vulnerable to other threats. Since Columbus arrived in the Caribbean in the 1490s, a number of nonnative mammals such as brown and black rat, feral cat, and dog, and small Indian mongoose, have been introduced into the region with devastating consequences for biodiversity in general, and Caribbean land mammals in particular. The threat of invasive species is particularly pressing for those hutia species which are restricted to small islands around Cuba. This is highlighted by the extinction of the Little Swan hutia in the 1950s following the introduction of cats onto Little Swan Island, Honduras. However, even for more wide-ranging species, invasive mammals may be having a long-term detrimental impact which is typically difficult to demonstrate. For example, there is evidence of widespread predation of Hispaniolan solenodon by domestic dogs in the increasingly fragmented forests of the

Dominican Republic, possibly leading to population extinctions in small habitat patches near human habitation.

Conservation Efforts

Conservation of the solenodons and hutias requires a combination of habitat protection, invasive species control and species-specific measures, such as raising awareness of the impacts of domestic dogs on these species in order to change husbandry practices and reduce predation rates. In the Dominican Republic, Cuba, and Jamaica many of the key habitats for solenodons and hutias fall within protected areas. However, management effectiveness of these areas is patchy with some high-profile national parks suffering from extensive illegal timber extraction, agricultural encroachment, and fires. There are also likely to be many undocumented populations of solenodons and hutias occupying smaller patches of habitat that occur outside of protected areas, which also require protection.

The control of invasive species, including their eradication from smaller islands, is a conservation priority in the Caribbean and it is urgently needed to save the most threatened hutia species in the islands off the coast of Cuba. For example, the Isla De La Juventud Tree hutia (*Mysateles meridionalis*), restricted to the Isle of Pines in Cuba, has declined dramatically through hunting and the impacts of rats. This species has not been seen by scientists in over 25 years and is likely to be on the brink of extinction. With possibly four hutia species on Cuban islets numbering fewer than 250 individuals, captive breeding represents an important tool for saving these species. Solenodons are difficult to keep and breed in captivity but hutias have proved more amenable, with Desmarest's hutia and the Jamaican hutia widely kept by zoos. Ingraham's hutia in the Bahamas has been captively bred and successfully translocated from its last remaining site of East Plana Cay to other cays in the archipelago in order to reduce its extinction risk.

Finally, another major threat to the Caribbean land mammals is a lack of awareness regionally and globally of their diversity, importance, and conservation requirements. They are a classic example of species which have been largely overlooked by the international conservation community and, if they are to be saved, it is vital that they are pushed up the conservation agenda.

Cheetah and African Wild Dogs

Background

The cheetah (*Acinonyx jubatus*) is Africa's most threatened large cat. The species has declined dramatically over the past century. Historically the cheetah was widely distributed throughout Africa, except for the central and western forest belts, and east through to India. Today the species has completely disappeared from most of its Asian range, only tiny populations remain in north and west Africa, and its main strongholds are concentrated in southern and eastern Africa (IUCN/SSC, 2007; IUCN, 2010). The species is classified as Vulnerable by the IUCN, with the Saharan and Asiatic subspecies listed as Critically Endangered, the latter persisting in a small remnant population in Iran. Cheetah are also listed on Appendix 1 in

CITES and are classified as an endangered Appendix 1 species by CMS.

African wild dogs (*Lycaon pictus*), though not closely related to cheetah, show a similar geographic distribution and face similar threats. Historically wild dogs were found throughout Africa south of the Sahara, absent only from the lowland forests of the Congo basin and the driest deserts. Today, the species resides in a small fraction of this historic range, mostly in southern and eastern Africa – only a handful of tiny populations remains in West Africa. The species is considered Endangered by the IUCN, and is listed on Appendix 2 of CMS. Both cheetah and wild dogs are now the subject of a range-wide conservation planning strategy, launched in 2007, which is an excellent example of conservationists addressing conservation challenges across a large scale.

Cheetah and wild dogs depend on small to medium sized antelopes for food. However, they are unusual among large carnivores in that natural populations are not limited by prey but by other large carnivores, particularly lions and spotted hyaenas (Durant *et al.*, 2010; Creel and Creel, 1996). These predators can kill adults and young, and also steal kills. Up to two-thirds of cheetah mortality in the Serengeti has been attributed to predation by larger carnivores, and this is also the most important cause of natural mortality among wild dogs. Perhaps as a consequence of avoiding larger carnivores, both cheetah and wild dogs range very widely, with home ranges up to 3000 km² having been documented (Marker *et al.*, 2008; Fuller *et al.*, 1992). Despite ecological similarities between cheetah and wild dogs, the two species have profoundly different social organizations. Female cheetah are solitary with overlapping home ranges, while male cheetah are often social, living in egalitarian coalitions of usually two to three males. Male cheetah can also hold territories, which are usually substantially smaller than female home ranges; in the Serengeti, male territories are on average less than 10% of the size of female home ranges. This combination of semisociality and ranging patterns has not been documented in any other mammal, and may be unique. It is thought that this unusual natural history has evolved as it enables cheetah, particularly females with vulnerable cubs, to access nomadic prey, whilst avoiding larger and more aggressive competitors such as lions and spotted hyaenas (Durant *et al.*, 2010). In contrast with cheetah, wild dogs are intensely social. Pack members cooperate to hunt, to defend their group territory, and to raise pups. Although reproduction is usually restricted to a single socially dominant pair, all pack members contribute to care of the pups and also feed the mother when she is confined to the den. Wild dogs have large litters, and the energetic demands of reproduction are consequently high; females are rarely able to raise pups alone, and larger packs experience higher reproductive success. Most young wild dogs leave the packs where they are born to seek breeding opportunities elsewhere, travelling as small groups of either males or females. These dispersal groups can travel hundreds of kilometers in search of mates and territories, and are sometimes sighted in regions where no resident populations have occurred for decades.

These features of cheetah and wild dog ecology place constraints on their abundance, with the result that natural densities of the two species in good habitat are usually substantially lower than those of other large carnivores such as

lions and hyenas. This has serious implications for the conservation of the two species. It is well understood that huge areas are required to conserve large carnivores, such as lions, tigers, and wolves; however, cheetah and wild dogs require conservation planning on an even larger scale. This means that protected area systems are unlikely ever to be sufficient for cheetah and wild dog survival. Indeed, today, only around a quarter of the world's remaining cheetah and 40% of the remaining wild dogs occur inside protected areas (Figure 8).

Threats

The main threats to cheetah and wild dogs today are habitat loss and fragmentation; habitat degradation; and retaliatory killing due to conflict with people and their livestock (IUCN/SSC, 2007). Historically, the captive trade was likely to have paid a strong role in the decline of cheetah. Cheetah were captured from the wild and used for coursing across much of Asia and the middle East. Akbar the Great reportedly kept a stable of 3000 captive cheetah in India. However, cheetah rarely bred in captivity, and the demand for cheetah is likely to have created a constant drain on wild populations. This was probably responsible for the massive contraction in cheetah range across Asia and northern Africa. Cheetah are rarely used for hunting today, but there are concerns that trade in cheetah may be increasing again, as the species is increasingly in demand for private collections (IUCN/SSC, 2007). Wild dogs are seriously affected by accidental snaring; they readily become captured in snares set for ungulates, and the resulting mortality has caused decline of several populations. Infectious disease – especially rabies – has also attracted attention as a threat to wild dogs, largely due to its role in the loss of wild dogs from the Serengeti in 1991.

Conservation Efforts

Cheetah and wild dog survival depends on ensuring the availability of large areas of suitable habitat, including protected areas as well as private or community areas where land use practices are compatible with the species' presence, such as livestock or game ranching. However, because cheetah and wild dog densities are low, it is critical that connectivity is maintained between smaller patches (<10,000 km²) of suitable habitat. Therefore transboundary cooperation, and the incorporation of the requirements of cheetah and wild dogs in national land use planning, are critically important. In order to address these challenges, a range-wide conservation planning process for cheetah and wild dogs was launched in 2007, followed by a conservation implementation phase launched in 2008. The planning process was designed to address the large area requirements of both species, and engaged national governments in a regional planning process to develop conservation strategies.

The cheetah and wild dog conservation planning process has two key themes: (1) an assessment of the current state of knowledge for both species; and (2) developing conservation strategies for the species. These themes are addressed in regional workshops in a participatory and consensual process which involves all key stakeholders, including national wildlife authorities, NGOs and species biologists. Participants in regional workshops are able to draw on at least some information on the effectiveness of particular tools for conserving

(a)

(b)

Figure 8 (a) Picture of a female cheetah with cubs. The cheetah is a large cat, built for speed, with long legs, small head, and flexible spine. Cheetah litters usually number from three to four cubs at birth, but can number up to seven. Because of high mortality, large litters of older cubs are unusual. Picture by SD. (b) Picture of African wild dogs interacting. Wild dogs are coursing predators which may chase their prey for several kilometers. This picture shows three members of a pack engaged in a “rally,” an enthusiastic greeting ceremony which precedes every hunt and illustrates the intense social bond which exists among pack members.

the two species, such as evaluations of methods for monitoring cheetah, and for addressing threats to wild dogs. To collate information on distributions a mapping process is used, based on one first used for jaguars by the Wildlife Conservation Society (Sanderson *et al.*, 2002). Workshop

participants map current knowledge of the extent of range for cheetah and wild dogs. This includes mapping areas where the species is known to occur and areas where it is known to be extirpated, as well as areas where information is unavailable (Figure 9). This then leads to discussion and agreement of a regional plan of action.

In both eastern and southern Africa, strategies identified the need to conserve cheetah and wild dogs outside protected areas, including finding ways to increase tolerance of these carnivores by local communities. Fortunately, unlike some other large carnivores, such as lions and leopard, cheetah and wild dogs do not pose a direct threat to people. However, both species can take livestock, and this causes conflict with livestock farmers. Moreover, the increasing popularity of game farms, particularly in southern Africa, can result in high levels of conflict as in these systems, farmers are ranching the natural prey of cheetah and wild dogs. In some areas, particularly those bordering protected areas, the appeal of the two species can be used to attract wildlife tourism, providing economic benefits to local communities. However, where this is not possible it is critical to reduce livestock loss and raise awareness of the importance of the survival of cheetah and wild dogs outside protected areas. Where meat from local livestock is exported, then accreditation schemes, such as cheetah friendly meat, may play an important role. This involves meat from farms which support cheetah commanding a premium from environmentally conscious consumers.

Regional and national workshops raise awareness of the conservation needs of the species, and enable the agreement of a plan of action by a range of stakeholders. However, there is a danger that planning exercises remain academic exercises; good on paper but never implemented. The cheetah and wild dog planning process is unusual because the planning is followed by a post-strategy implementation phase. This enables national governments to develop their own national conservation action plans for cheetah and wild dogs in line with a regional strategy, facilitating transboundary cooperation. Regional coordinators have been appointed to ensure that national action plans are established across cheetah and wild dog range following on from the regional strategies, and that they are implemented.

By the end of 2010, national plans had been developed in 10 of the 13 known cheetah and wild dog range states in Eastern and Southern Africa, covering 72% of current known cheetah range. Regional offices had been established in eastern and southern Africa, helping overstretched wildlife authorities to prioritize cheetah and wild dog conservation over a plethora of competing interests. The project has focused on improving capacity for cheetah and wild dog conservation within the range states, and acts as a model for the conservation of other wide-ranging terrestrial species.

Themes of the Case Studies

One of the main overarching themes from all three case studies is the paramount need to consider human needs and incentives (financial or otherwise) when designing conservation interventions. Human activities, whether direct exploitation or habitat conversion, are at the root of the

Figure 9 Map of the range areas of (a and b) cheetah and (c) wild dog in eastern and southern Africa in 2008, based primarily on the information provided at the planning workshops (reproduced from IUCN/SSC (2007) *Regional Conservation Strategy for the Cheetah and African Wild Dog in Eastern Africa*. Gland, Switzerland: IUCN Species Survival Commission).

problems that the case study species face. Changes in attitudes and improved knowledge of the needs of the species can lead to changes in behavior by people living in the area, which is required if these species are to have a sustainable future in the long term. However, change in the behavior of individual people is not enough. External events, such as the break-up of the Soviet Union for saigas, or the ongoing poverty and disasters faced by Haiti, are not easily addressed by projects targeting particular species. Similarly, the future of wide-ranging species such as the cheetah and wild dog can only be secured if conservation is planned and implemented at a landscape scale, involving the participation of multiple range states. In the case of the saiga, relatively small-scale conservation efforts at the local level saw the species through the dark times until the economic and social situation stabilized and larger-scale conservation efforts were able to step in.

In the case studies which we have discussed, the focus of conservation efforts has been on single species. However, in the case of both saigas and cheetah and wild dogs, the species are being used as flagships for wider landscape-scale conservation. This leads on to the necessity for an ecosystem approach to conservation, in which the interlinkages between species and their habitat are at the forefront. Perhaps the conservation of mammals has retained its single-species focus for longer than in other taxonomic groups because of their charismatic nature, and the potential that they have as flagships. Even the small and cryptic hutias and solenodons are potentially flagships for the conservation of their habitat due to their ancient lineage, fascinating biology, and odd appearance.

The case studies also highlight the importance of understanding the biology of the system and of the species themselves in order effectively to plan conservation actions. In the case of the Caribbean mammals, one of the main impediments to conservation is that the species are very poorly known; there are a number of these species which may or may not be extinct, their distributions are not well understood and very little is known about their ecology. In these circumstances, conservation actions must include basic research. The saiga is much better known, but even for this species, distributions, movement ecology, and population sizes are still unclear, because the species is nomadic, ranging widely, and crossing national boundaries in their seasonal migrations. The hutias and solenodons also highlight the importance of captive breeding as a safety net for species that are restricted to single sites, exist in very low numbers and for which the *in situ* threats are extreme. Saigas and cheetah breed poorly in captivity, and remain at relatively high numbers in the wild, demonstrating that captive breeding is not an appropriate solution for all species. In all cases, understanding species' biology is not enough; conservation scientists also need to carry out research to understand the social and economic dynamics of the system in order to be able to target conservation action at the right people. For example, cheetah and wild dog conservation involves gaining the support of livestock farmers and game ranchers, because protected areas alone cannot support adequate populations of the species.

As information accumulates about the needs and distribution of species and the attitudes and circumstances of the people living with them, it is important to reassess priorities

and approaches. The cheetah and wild dog planning workshops are an excellent example of taking a strategic approach to conservation, at an appropriate scale. Similarly, the periodic reassessment of conservation progress and priorities that is facilitated by the CMS's saiga conservation MOU is very useful in ensuring that conservation is tailored to the circumstances that the species faces. In the case of the saiga, conservation is moving from emergency mode into a stage when conservationists are able to think ahead and plan strategically for the future, including ensuring that protected area networks are robust to climate change and that the cost-effectiveness and impact of their interventions are properly evaluated.

All three case studies involve species that are found in relatively low-income areas and in places where the capacity to carry out research and conservation is limited. This includes the technical capacity to carry out tasks such as GIS mapping, the financial capacity to fund the research and conservation that is required, and the administrative capacity to implement conservation action. In each case, the conservation process has included supporting these countries to build their capacity, with the goal of enabling countries to manage their own biodiversity in collaboration with others, rather than relying on outsiders. Ensuring that countries feel ownership over their science and conservation is the only way to ensure sustainable conservation in the long run. International processes in which stakeholders meet to agree on priorities and activities and can coordinate their efforts across boundaries are crucial. This may apply less to the Caribbean mammals, although Hispaniola is an example in which the Haitian and Dominican Republic governments share conservation problems which require a joint solution.

Conclusions

Terrestrial mammals are often used as flagship species for conservation. The classic example of this is the panda used by WWF, but tigers, elephants, whales, great apes, and other charismatic species are also featured in publicity material about conservation because they are appealing to the public. Many people, particularly in wealthier countries, place very high intrinsic values on mammals and are extremely keen to preserve them and to ensure the welfare of individual representatives of the species. Other people, particularly those who live alongside wild mammals, may be very keen to use them, or to get rid of them. Many mammals are economically valuable because of their meat, furs, or trophies, or are destructive neighbors that invite persecution. At the same time, because of their biology, these species can be very susceptible to persecution or overexploitation.

These factors combine to make many mammals high-profile species among both the general public and conservationists. They often provide a battleground on which conservation battles of more general significance are fought. An example of this is the highly charged and public debate about the listing of the African elephant on the CITES Appendices. This began in 1989 with a successful proposal to transfer the species from Appendix II (controlled international trade) to Appendix I (no international commercial trade), on the basis that the elephant was threatened with extinction

from an uncontrolled, and largely illegal, international ivory trade. The ensuing public debate aired issues ranging from the principles of sustainable use, national sovereignty over resources, animal welfare and animal rights, bringing relatively sophisticated arguments to a wider audience. In March 1999, CITES agreed to a limited resumption of ivory sales, several of which have taken place since then. Much investment has gone into large scale monitoring of the ivory trade and of illegal killing of elephants, in an attempt to understand whether CITES actions have had an effect on elephant poaching. Although this is a hugely complex task, due to the many confounding factors, the recognition that conservationists need scientifically to assess the effects of conservation interventions is an important one (Burn, 2007).

Mammal conservation is high profile and an area in which much general conservation policy is debated and eventually made. The danger is that this policy may not be at all relevant to other components of biodiversity, with their own specific conservation requirements and biological peculiarities. Policies made with respect to one high-profile mammal species may not even be positive for other mammals. Flagship species have to be chosen wisely, since experience shows that species' conservation needs cannot be predicted from their body size or trophic position. For example, in the 1980s, India designated a network of reserves designed to protect tigers, under the banner of "Project Tiger." The project was expected to have the added benefit of protecting other species, including the dhole, a species of wild dog. This expectation was not met; dhole require much larger areas to persist than do tigers and have disappeared from several Project Tiger reserves (Woodroffe and Ginsberg, 1998).

Conservation efforts for mammals are particularly noteworthy because of their impacts on biodiversity conservation in general. This is partly because mammals can be powerful forces structuring ecosystems. But it is also because they are often flagship species for conservation policy; this can be a mixed blessing for the conservation of biodiversity as a whole, as policy made with one particular group of species in mind will not necessarily be appropriate for others. Though this calls for caution in extrapolating the needs of mammals to conservation policy on the broader scale, it is also important to remember that mammals are particularly in need of conservation efforts in their own right, and that some mammal species, particularly small and cryptic ones, are still largely ignored both by conservationists and the general public.

Glossary

Baiji The species of marine mammal also known as the Yangtze River dolphin or Chinese river dolphin, *Lipotes vexillifer* Miller, 1918, the sole member of the odontocete cetacean family Lipotidae. The last living baiji was seen in 2002, and the species was reported by experts to be extinct in 2007. This was the first known extinction of a cetacean species in recorded human history, and the fourth known extinction of a marine mammal species since the eighteenth century AD.

Baleen Modified, hardened epithelial structures suspended from the upper jaws of the mysticete whales. Baleen is in the form of multiple elongate plates within mysticete whale mouths, with a fibrous fringe on the inside edge that allows whales to filter zooplanktonic or fish prey from sea water.

Cetacea The order of mammals that includes the whales, dolphins, porpoises, and allies.

Delphinidae The family of odontocete cetaceans that includes the dolphins. Delphinids are the most diverse family of marine mammals with 36 species currently recognized, approximately 28% of the known modern species of marine mammals.

Desmostylia The only known fully extinct order of marine mammals, closely related to the sirenians. Desmostylians were large herbivorous quadrupedal animals living in shallow waters during Oligocene and Miocene times, possibly resembling the modern hippopotamus superficially in ecology, behavior, and appearance. Desmostylians are known in the fossil record only from coastal regions of Washington and Oregon, USA.

Mysticeti The suborder of cetacean that includes the four families of baleen whales. Most mysticetes are quite large, including the blue whale which reaches 33 m in length and is recognized as the largest animal in the earth's history. Approximately 9% of the known modern species of marine mammals are mysticetes.

Odontoceti The suborder of the cetacean that includes the 10 families of toothed whales, including sperm whales, beaked whales, dolphins, porpoises, belugas, narwhals, and river dolphins. Approximately 56% of the known modern species of marine mammals are odontocetes.

Pinnipedia An obsolete but frequently used taxonomic term for the three families that comprise the seals, sea lions, fur seals, and walrus. Approximately 28% of the known modern species of marine mammals are pinnipeds. All pinnipeds are in the mammalian order Carnivora.

Scientific whaling Whaling activity currently undertaken by the Institute of Cetacean Research (Japan) with the stated goal of improved understanding of relationships of large whales and marine ecosystems in the world's oceans. The activity is permitted under a procedural exception to the moratorium on commercial whaling as managed by the International Whaling Commission. Scientific whaling is highly controversial and under ongoing intensive debate among scientists, management organizations, conservation advocacy groups, government agencies, politicians, and the public at large, and there is widespread concern that the activity may facilitate development of illegal trade and export of whale products, possibly leading to uncontrolled and damaging illegal harvests of whales.

Sirenia The order of mammals that includes the manatees, dugongs, and sea cows.

Introduction

Taxonomic Definition of "Marine Mammals"

The "marine mammals" include one extinct order and three major extant taxa that were or are fully aquatic, in most cases occurring entirely in the marine habitats of the major ocean basins and associated coastal seas and estuaries. In addition, a few species of largely terrestrial taxa are currently regarded as marine mammals. We consider 127 Holocene mammal species in total to be marine mammals for purposes of this review (Rice 1998; see also Reeves *et al.*, 2002, and Jefferson *et al.*, 2008, for excellent non-technical accounts). We acknowledge that species numbers within any taxon are subject to virtually continuous revision as new systematic methods and philosophies emerge. Our primary bases for defining our list of

marine mammal species are the protocols of the US federal government, defined by the US Marine Mammal Protection Act (MMPA) of 1972 (16 USC §§1361–62, 1371–84, and 1401–07 (Supp. IV 1974)) as amended (MMPA) and managed by two US federal agencies: the National Marine Fisheries Service (NMFS) and the Fish and Wildlife Service (FWS). Our principal source for taxonomic nomenclature, including common names, is the review of Rice (1998).

The order cetacea includes the whales, dolphins, porpoises, and their allies (Table 1). The "pinnipedia" is a group of species in three families in the mammalian order carnivora (Table 1). The pinnipeds include the seals, fur seals, sea lions, and allies. The order sirenia includes the extant manatees and dugong, and the now-extinct Steller's sea cow (Table 1). The order desmostylia is the only recognized order of marine mammals to become entirely extinct.

Two largely terrestrial families of the order carnivora include species recognized as marine mammals (**Table 1**). The sea otter and chungungo (family mustelidae) live entirely or primarily in marine habitats. The polar bear

^aThe indicated species was last observed in natural habitat in 2002 and is considered extinct.

^bOne of the indicated species, the Japanese sea lion, was last observed in natural habitat in 1951 and is considered extinct.

^cOne of the indicated species, the Caribbean monk seal, was last observed in natural habitat in 1952 and is considered extinct.

^dOne of the indicated species, the Steller's sea cow, was last observed in natural habitat in 1767 and is considered extinct.

(family ursidae) spends a significant proportion of time at sea as well.

Many other species of mammal utilize aquatic or marine habitats, including monotremes, ursids, mustelids, canids, primates, rodents, bats, and ungulates, among others. Ultimately, the distinction among aquatic, marine, and terrestrial taxa is arbitrary. Thus, our reliance on definitions and protocols of MMPA, NMFS, and FWS is subjective, although largely consistent with common practice among most specialists.

We use the term "marine" to refer to large, contiguous aqueous habitats with significant dissolved salt content in ambient waters, including the world's oceans, seas, and estuaries. We apply the term "aquatic" to aqueous habitats without significant measurable dissolved salt concentrations in ambient waters, such as lakes and rivers above the point of significant mixing with marine waters, and to inland saline lakes that lack outlet streams connecting to marine habitats. "Terrestrial" habitats are those lacking standing water under normal circumstances.

General Features and Habitat Boundaries

Marine mammals are characterized by a number of striking modifications, as compared with terrestrial mammals, in anatomy, physiology, and ecology (**Table 2**). In some cases, the modifications are sufficiently extreme that phylogenetic linkages to terrestrial ancestry are obscured, difficult to resolve, and matters of controversy among scientists. The degree of modification is correlated with the duration of the evolutionary history of the major marine mammal taxa as marine organisms.

Although marine mammals are largely defined by marked departures from the terrestrial mammalian model, it is instructive to consider the major features of terrestrial mammals retained in marine mammals. In the context of extinction processes in general, and anthropogenic extinctions in particular, two retained features are of particular importance. First, although most marine mammals spend most of their lives immersed at sea, they retain a largely terrestrial respiratory architecture and must surface and breathe in order to allow for exchange of respiratory gases. Second, marine mammals are homeothermic, with core body temperatures typically near 38 °C, like their terrestrial relatives. The need to breathe at the surface and the need for major anatomical

adjustment to minimize rates of heat loss are constraints that foster vulnerability to unsustainable rates of exploitation and to certain types of pollution. The significance of these constraints is developed in the case studies we present in this article.

The diving capabilities of marine mammals define the three-dimensional nature of their habitats at sea. Nearly all extant marine mammals dive to forage, although the ranges of diving capability and pattern are broad. Most marine mammals also spend significant time submerged while traveling, socializing, or breeding.

Among the cetaceans, sperm whales, beaked whales, and narwhals likely dive deeper and longer than other species on average. Sperm whales can dive to 3000 m, remaining submerged for an hour or more. The diving behavior of beaked whales is poorly known, but there is emerging evidence that beaked whales also may routinely make repetitive dives of long duration to great depth. Narwhals are known to be capable of dives of 1800 m depth and may dive to depths in excess of 1000 m 20–30 times per day. Most baleen whales and many of the smaller cetaceans commonly dive for less than 10 min at a time, and to depths no greater than a few hundred meters.

Among the pinnipeds, the elephant seals (in the family phocidae) have maximum diving capabilities to nearly 2000 m, and are known to make remarkably long sequences of repetitive deep (400–600 m), long (20 min or more) dives with surface intervals of only 2–3 min. These sequences may be maintained day and night for tens of days at a time. Many other phocid seals are thought to have similar capabilities. The sea lions and fur seals (otariidae), in contrast, generally dive for only a few minutes at a time, and generally to maximum depths of a few hundred meters, although many otariids are known to be capable of continuous sequences of repetitive shallow dives of 10–12 h or more.

In contrast to cetaceans and pinnipeds, sirenians are weak divers, generally remaining in shallow water (<20 m) and diving only for 2–3 min when active. Deeper dives (to 70 m) may occur on occasion, and dive duration can be quite long (>1 h) when animals are resting at the bottom. Sea otters are also relatively weak divers, reaching depths of 100 m and remaining submerged for a maximum of approximately 5 min, although most dives are to 30 m or less and last only for 1–2 min. There are no data available on the diving capabilities of the chungungo.

Few field observations of Steller's sea cow were made before extinction, but morphological analysis suggests that sea cows were unable to dive below the sea surface, surviving instead by foraging on kelp forest canopies and other macroalgae floating on the sea surface. Polar bears are able to make shallow dives, but do not typically engage in the extended repetitive dive sequences typical of many marine mammals, and apparently do not forage while diving. Polar bears instead use stealth, quickness, and great strength to capture phocid seals, their primary prey, at seal breathing holes on the ice surface. Thus, the extent to which the at-sea habitat of marine mammals is truly three-dimensional varies widely among the major taxa as well as the individual species. Within species, there is marked ontogenetic variation in diving capability and pattern as well.

The marine mammals are geographically ubiquitous in the world's oceans, seas, and estuaries (e.g., Perrin *et al.*, 2009). Cetaceans occur in marine environments at all latitudes. For example, killer whales may have the largest natural geographic range of the earth's mammals. Most of the mysticetes and some of the larger odontocetes have global ranges or are distributed antitropically. Smaller cetaceans are widely dispersed as well, although individual populations typically concentrate in regions of predictably high local biological productivity. Several species of small cetaceans, including delphinids, phocoenids, and the three extant monotypic families of river dolphins, are found in major river systems in South America and Asia. Pinnipeds occur in all the world's major marine habitats, but most species are concentrated in middle or high latitudes, in close association with regions of high productivity (e.g., Kovacs *et al.*, 2011). In addition, there are several pinniped species or populations confined to isolated large lakes in Europe, Asia, and North America. Most sirenians are confined to tropical or subtropical latitudes, in shallow seas that provide adequate macrophytic food and refuge from predation, and are thermally tolerable. The sea otter is confined to the coastal North Pacific Rim, and the chungungo to the temperate coastal southeastern Pacific. Polar bears occur only in the Arctic and sub-Arctic, rarely traveling south of 60° N latitude except in the relatively frigid northwestern Atlantic and Hudson Bay.

Cetacea

The distinguishing anatomical and functional features of the cetaceans are summarized in Table 2. The two major taxonomic subdivisions of cetaceans are the suborders odontoceti, or "toothed whales", and mysticeti, or "baleen whales". The odontocetes are the most diverse of the major Holocene marine mammal taxa, with 10 families and 71 species. The best-known families are the delphinidae and phocoenidae (Table 1). In ecological terms the family ziphiidae is among the most sparsely studied groups of mammals on earth. Other odontocetes include the sperm whales, beluga whales, narwhals, and river dolphins. The mysticetes (Table 1) include species that are the largest animals in the earth's history, with the largest of all, the Antarctic blue whale, reaching 33 m in length and 150,000 kg in mass.

Most cetaceans dwell in the open sea, or in the seas and estuaries of the continental margins. The exceptions are two delphinids, a phocoenid, and three odontocete species known as river dolphins (Table 1). Of the river dolphins, one species, the Franciscana or La Plata dolphin, may be found in coastal marine waters of Brazil, Uruguay, and Argentina. The other two river dolphins are exclusively aquatic. One of these, the boto, is known to leave river channels and travel within the adjacent flooded forests of the Amazon basin during the wet season. The Irrawaddy dolphin, a delphinid, occupies estuarine habitats and major river systems in southeastern Asia. The tucuxi, another delphinid, occupies the Amazon watershed and coastal marine habitats of tropical Atlantic South America. The finless porpoise, a phocoenid, occurs in the Yangtze River watershed and other large southern Asian rivers, and coastal marine habitats from the Persian Gulf to Japan.

Mysticetes often segregate feeding and breeding activities, both in time and space, connecting the two categories of

activity with extensive seasonal migration. Feeding is done primarily at high latitude during summer, and breeding and parturition primarily at low latitude during winter. Thus, a significant poleward migration is required during spring, and an equatorward return trip is necessary in autumn. The segregation of feeding and breeding, and the associated migratory behavior, is best developed and understood in the largest cetaceans. However, some large mysticetes, such as the bowhead whale of the Arctic region and the Bryde's whale of tropical and subtropical latitudes, undertake only modest seasonal migrations in contrast to species such as the humpback whale or gray whale. The smaller cetaceans, including most of the odontocetes, appear to disperse primarily on the basis of food availability and productivity at sea. Odontocetes typically do not engage in the dramatic seasonal migrations known for some of the mysticetes, although there are exceptions among the larger species.

Healthy mysticetes never leave the water, nor do they attempt to leave the water, in favor of land. A few odontocetes occasionally strand intentionally on beaches or river banks while in pursuit of prey. Perhaps the most familiar example is the brief intentional stranding of individual killer whales (*Orcinus orca* (Linnaeus, 1758)) while foraging on pinnipeds in the surf zone of Argentine beaches. In general, the cetaceans are not functionally amphibious. Aside from the noted exceptions, strandings of cetaceans can be considered abnormal, even pathological behavior typically resulting in death or serious injury.

Pinnipedia

The pinnipeds have a shorter evolutionary history as marine mammals and are derived from different ancestral taxa than the cetacea. Thus, although pinnipeds and cetacea often use similar aqueous habitats, the pinnipeds have many obvious differences from the cetacea in form and function. Features shared by most pinnipeds, including the phocids, otariids, and odobenids, are summarized in Table 2. The largest pinnipeds are adult males of the highly dimorphic southern elephant seal, exceeding 5 m in length and reaching 3700 kg in mass. Adult male northern elephant seals are only slightly smaller. Walruses are also quite large, reaching 3.5 m and 1500 kg.

Despite many anatomical, physiological, and ecological features obviously associated with life at sea, pinnipeds are best regarded as amphibious. All species utilize solid substrata for breeding and for postbreeding maternal care. Solid substrata are used also as short-term resting sites, and for protracted periods during molting of the skin and pelage. Although the proportion of time spent on land ("hauled out") over the long term varies significantly among age and sex categories, generally, the pinnipeds spend a major portion of their lives on land near shore, or on pack or shorefast sea ice.

Otariids use terrestrial habitats near shore for breeding, *post partum* maternal care, molting, and resting. Preferred hauling sites are those near areas of high oceanic productivity and free of large terrestrial predators. Thus, hauling grounds for otariids typically are islands or mainland locations protected by cliffs or rough terrain from land predators. Often the hauling grounds are localized at high latitude or the upwelling zones of midlatitude eastern boundary currents, such as the Humboldt, California, and Benguela currents, where production of

preferred food species is high and temporally predictable. Optimal hauling grounds for breeding otariids are few in number, and often limited in size. Breeding activities of otariids are highly synchronous, occurring during a narrow time window when food availability for lactating females and newly produced juveniles is seasonally optimal. As a consequence of the various spatial and temporal constraints, pinniped breeding often involves conditions of extreme crowding on haulout sites.

Phocids and walruses haul out for the same purposes as do the otariids. Unlike otariids, the phocids and walruses use two different kinds of substrata. About half the phocid species use coastal land for hauling grounds, selecting sites for largely the same reasons as described for the otariids. Thus, timing and location of breeding for land-breeding phocids and otariids are generally similar. As a consequence, reproductive activities for many land-breeding phocids also occur under conditions of extreme crowding. Known exceptions include some populations of harbor seals with spatially dispersed, largely aqueous breeding systems, and the two extant species of monk seal with temporally asynchronous breeding systems at low latitude. The walrus and the remaining phocids breed, care for young, rest, and molt on ice at high latitudes rather than on land. Ice as a substratum varies widely over time and among locations in stability, vulnerability to predators, and provision of access to the surrounding sea. Thus, among ice-breeding pinnipeds, there are significant resultant variations in social and breeding strategy, and the degree of crowding at hauling sites. A major predator of ice-hauling phocids, the polar bear, is present in ice-covered marine habitats of the Arctic region, but not the Antarctic. This pattern has a number of interesting consequences for interhemispheric differences in the ecology of ice-hauling pinnipeds.

Some phocid species or subspecies occur only in aquatic habitats. Two subspecies of ringed seal occur only in Lake Saimaa, Finland, and Lake Ladoga, Russia, respectively. The Caspian seal is found only in the Caspian Sea, and the Baikal seal only in Lake Baikal, both in Russia. A population of harbor seals occurs year-round in Lake Iliamna, Alaska, but the degree of exchange, via river connection to populations of harbor seals in the nearby Bering Sea, is unknown.

Sirenia

Several of the defining anatomical and functional features of the sirenians (Table 2) are convergent with those of the cetaceans. However, in contrast to the cetaceans, there are few Holocene sirenians (Table 1). The sirenians are the only herbivorous marine mammals, sharing common ancestry with the desmostylians and the terrestrial subungulates (e.g., elephants and hyraxes).

Sirenians are large in body mass and linear dimension compared with most terrestrial mammal species. The Steller's sea cow was the largest of the Holocene species, reaching 7 m in length. Body mass of the Steller's sea cow was never directly measured, but the estimated maximum is 10,000 kg. Maximum adult lengths and masses of the three manatee species range from 3 to 4 m and 450 to 1600 kg, respectively. Adult dugongs reach maxima of 3.3 m in length and 400 kg in mass.

All modern sirenians are fully aquatic or marine, and are incapable of leaving the water. Sirenians feed on large plants

growing on the sea bottom, in midwater, at the surface, or closely overhanging the surface. They forage exclusively in shallow habitats. Manatees utilize freshwater, estuarine, and fully marine habitats, often interchangeably. They generally concentrate in habitats that are relatively warm and physically protected from extremes of weather and sea. Dependence on relatively warm water temperatures may result from the combination of obligate homeothermy and a relatively low basal metabolic rate, possibly a consequence of herbivory, compared with other marine mammals. The limited tolerance of low water temperature likely contributes to seasonal migration, and a tendency to concentrate at high density in warm water refugia during the winter. Manatees may also congregate near sources of fresh water, although fresh water is not a physiological requirement. The smallest of the modern sirenians, the Amazonian manatee, occurs only in the freshwater habitats of the Amazon River watershed of South America. Dugongs are fully marine and forage primarily on benthic seagrasses in shallow coastal tropical marine habitats. Steller's sea cow, known only from the sub-Arctic Northwest Pacific, was the most aberrant of the Holocene sirenians. Sea cows likely foraged exclusively on canopy-forming kelps and other large algae along exposed shores.

Desmostylia

Desmostylians are the only known extinct order of marine mammals. The small numbers (< 10) of recognizable species in the fossil record are of Oligocene and Miocene age, and are confined geographically to the North Pacific region. Desmostylians were quadrupedal amphibians sharing common evolutionary ancestry with the sirenians. Habitats of desmostylians probably were shallow waters supporting productive populations of algae and aquatic vascular plants, their primary food, in latitudes ranging from subtropical to cool temperate. In habits and superficial morphology, desmostylians are often characterized as being similar to the modern hippopotamus. Some have argued that at least some of the desmostylians fed on clams and other benthic invertebrate prey, but the consensus view is that they were primarily, if not strictly, herbivores.

Marine Otters

There are 13 recognized extant species of otter worldwide, comprising the mustelid subfamily Lutrinae. Here we consider two species: the sea otter (*Enhydra lutris* (Linnaeus, 1758)) of the North Pacific Rim and the chungungo (*Lontra felina* (Molina, 1782)) of Peru, Chile, and southernmost Argentina. Both are marine species with amphibious characteristics. Other otter species may utilize marine environments, but they also have obligatory associations with aquatic and terrestrial habitats. The sea otter and chungungo do not appear to utilize freshwater habitats, except occasionally and facultatively.

The sea otter is arguably the most derived of the lutrines. It is the largest of the mustelids in mass, with some adult males reaching 45 kg in mass and 1.6 m in total length, but among the smallest of the marine mammals. Sea otters are relatively weak divers compared with most marine mammals, and feed almost entirely on large-bodied sessile or slow-moving benthic invertebrates. Sea otters often haul out on coastal beaches and reefs to rest and conserve heat, especially in the northern

portions of their geographic range during periods of harsh weather or reduced sea surface temperature. Sea otters are not known to utilize freshwater habitats for any purpose.

The smallest of the marine mammals, the chungungos reach maxima of 6 kg in mass and 1.1 m in length as adults. Chungungos are morphologically similar to the other seven species in the genus *Lontra*. The ecological characteristics of chungungos are not well known. They feed primarily on small crustaceans, molluscs, and fish taken during dives in near-shore marine habitats along open coasts. They may also forage in fresh water, taking small crustaceans. They haul out between foraging periods on exposed rocky shores, and maintain shoreline dens that are the focal areas for social and reproductive behavior. Chungungos produce litters of two to four pups with a mean of two, and are one of only two marine mammal species (polar bears are the other) with a litter size typically greater than one.

Polar Bears

Polar bears are one of seven recognized bear species. Several of the other bear species utilize marine and aquatic habitats for foraging, but polar bears are more dependent on marine habitats for food than other bears. Along with chungungos, polar bears are perhaps the least modified morphologically, compared with terrestrial mammals, of the world's recognized marine mammal species. Although generally similar to other bears morphologically, polar bears have several distinguishing features that reflect their associations with frigid terrestrial and sea ice habitats, and with Arctic marine ecosystems. Polar bears are small compared with many marine mammals, but large compared with most other bears. Adult males reach 2.5 m in length and 800 kg in mass. Although polar bears do not dive repetitively in the manner typical of many marine mammals, they are efficient swimmers, able to traverse large expanses of open water. Polar bears also cover large distances at sea by walking or running across sea ice. Although primary prey species are pinnipeds taken from the surface on sea ice, polar bears are capable of supplementing the diet from other sources. They are the only recognized species of marine mammal that travels extensively on land away from the shoreline, and the only species that consumes both plant and animal species as a regular part of the diet. In addition, polar bears are unique among marine mammals in producing altricial young. Litter size ranges from one to three, with a mean of two, and may be linked to maternal body condition and the availability of food.

Synopsis of Evolutionary Histories of Major Marine Mammal Taxa

Cetacea

The oldest recognized cetaceans are Eocene fossils of the cetacean suborder Archaeoceti. Archaeocete fossils are found primarily in rocks of present-day Egypt, Pakistan, and India, in strata thought to be associated with the Tethyan Sea of ancient times. Thus, it is thought that cetaceans originated in the Old World Tethyan environment and share common ancestry with an extinct terrestrial ungulate taxon known as the mesonychians. The earliest recognizable cetacean fossils date to

approximately 50 mybp. The archaeocetes included a number of "missing link" species, displaying intermediate forms indicating progressive reduction and loss of the hind limbs, development of the caudal spine and flukes for propulsion, elongation of the anterior skull, and simplification of dentition.

The archaeocetes were largely extinct at the beginning of the Oligocene, approximately 38 mybp. The first precursors to the modern suborders odontoceti and mysticeti appear in the fossil record during the Oligocene, but the first fossils linked unambiguously to modern cetacean families appear primarily during the Miocene. For example, the earliest sperm whales appear in early Miocene strata. Beaked whales appeared first in the middle Miocene, and the earliest dolphins and porpoises in the late Miocene of approximately 11 mybp. In the mysticetes, the earliest rorquals and right whales are also in Miocene strata. The oldest identified gray whale fossils are from the Pleistocene, and there are no known fossils providing insight into the early evolution of the modern gray whales.

Although evolutionary linkages across the history of the cetacea are uncertain at best and often entirely unclear, it is apparent from the fossil record that the modern taxa of cetaceans have been preceded by many extinct species, likely outnumbering extant species by a considerable number. For example, an early mysticete group, the family cetotheriidae, contains approximately 60 known species dating from the Oligocene. Such extinct large taxa imply significant episodes of diversification and subsequent extinction well before the modern families of cetaceans appeared. The record also suggests a dynamic pattern of biogeographic variation, such as the occurrence of ancestral monodont (the family that now includes only the belugas and narwhals of high northern latitudes) fossils in Miocene strata of Mexico. The dynamic evolutionary record almost entirely predates hominid evolution and the emergence of anthropogenic influences on patterns of extinction.

Pinnipeds

The earliest known pinnipeds are represented by fossils of the late Oligocene or early Miocene, approximately 25 mybp. The two major recognized lineages culminate in the modern phocidae and the modern superfamily otarioidea, the latter including the otariidae and the odobenidae. The earliest fossils of both lineages are of similar late Oligocene or early Miocene age. In contrast to the cetaceans, there are recognized linkages of good quality between the earliest pinniped fossils and the major modern pinniped taxa.

The traditional view of pinniped evolution is that the phocids and otarioids evolved independently. Phocids are said to have emerged in the North Atlantic region from ancestral forms linked to modern mustelids. The appearance of phocid species in the Pacific likely occurred much more recently, possibly in events related to the extinction of early Pacific otariids and odobenids. Otarioids are thought to have evolved from ancestral ursids in the North Pacific. The diphyletic model is supported by traditional analyses of cranial morphology and by the absence of early fossil otarioids from strata of the North Atlantic region. Recent analyses of postcranial material and of molecular data support an alternative model in

which the pinnipeds are a monophyletic lineage sharing common ancestry with the modern mustelids. Current consensus favors the monophyletic model.

Recently published evidence indicates controversy over the affinities of the odobenidae. Some analyses indicate that the odobenids are in fact more closely related to the phocids than the otariids, whereas others favor the more traditional view, with odobenids closely allied to otariids in the otarioidea. We follow the traditional view here, but acknowledge the evidence in support of the alternative scenario.

Ancestral taxa of otariids and odobenids show a high level of diversity compared with modern forms. The recognized modern genera of odobenids and otariids appeared primarily during the late Pliocene or the Pleistocene. The fossil record for phocids is not well developed, especially in some North Atlantic regions thought to be important in understanding early evolution in the group. Miocene fossils from the southern hemisphere include significant numbers of monachine (phocid subfamily monachinae) seals, ancestral to the Holocene monk seals, elephant seals, and Antarctic ice seals. Ancestry and relationships of the more derived forms, including the modern phocine (phocid subfamily phocinae) seals of northern temperate and polar latitudes, have not been resolved definitively. As with the cetaceans, the pinniped fossil record indicates significant episodes of diversification and extinction before the emergence of the Holocene forms, and clearly predating anthropogenic influences.

Sirenians

The earliest fossil sirenians are from early Eocene strata, approximately 55 mybp. Significant radiation into at least three families had occurred at the time the earliest cetacean fossils appear in the middle Eocene. Thus the sirenians appear to be the oldest order of living marine mammals on earth. The fossil record does not provide clear evidence of the ancestral groups that gave rise to the sirenians, although studies of modern forms indicate common ancestry with the other subungulates. Although the oldest sirenian fossils are from Jamaica, the sirenians are thought to have emerged first in the Old World Tethyan environment. The early radiations of the sirenians appear to share common ancestry with the extinct family protosirenidae. The protosirenids appear to have given rise to the modern families trichechidae (manatees) and dugongidae (dugongs and sea cows). Dugongids probably first appeared in Mediterranean waters during the Eocene, whereas trichechids apparently first evolved along the South American coast during the Miocene. Sea cows first appeared in the southeastern Pacific during the early Miocene, later radiating throughout the Pacific basin. Some sea cows were unusual among sirenians in their great body size and use of relatively exposed cold-water habitats. They occurred along the coasts of California, Japan, and the sub-Arctic North Pacific Rim during the Pliocene and Pleistocene. Although the predominant sirenian family in the Holocene, the trichechids have a relatively poor fossil record. The allopatric distribution of the three modern species resulted from temporary geological isolation of the Amazonian watershed, and from a chance colonization of West African coastal waters from an ancestral Caribbean population.

Desmostylians

As noted above, the desmostylians apparently first appeared in the oligocene, approximately 35 mybp. The oldest known fossils are from the coasts of Washington and Oregon in the Northeastern Pacific, and all desmostylian fossils come from the North Pacific. The desmostylians share common ancestry with the sirenians and terrestrial subungulates, although many details of these relationships are unknown.

Marine Otters and the Polar Bear

The sea otter, chungungo, and polar bear represent three separate, relatively recent entries into marine environments by largely terrestrial or aquatic taxa. Chungungos still resemble other otters so closely that a meaningful fossil record of their evolution as marine mammals does not exist. There are some Pleistocene fossils of polar bears, but neither fossil nor modern forms represent significant departures from the ancestral ursid morphology. Thus, for both chungungos and polar bears, the history of adaptation to marine life is best inferred from modern biological data.

The sea otter appears to have a somewhat more extensive fossil ancestry, in the marine environment, than the polar bear or chungungo. There are two extinct genera of sea otters in the fossil record. Seven fossil species of *Enhydriodon* have been found in Africa and Europe, in late Miocene and Pliocene strata. *Enhydritherium iluecai* (Villalta Comella and Crusafont Pairó, 1945) is known from the late Miocene of Europe, and *Enhydritherium terraenovae* (Berta and Morgan, 1985; Berta *et al.*, 2005) from the late Miocene through the middle Pliocene in Florida and California. *Enhydritherium* is thought to be a direct ancestor of *Enhydra*. *Enhydra* is confined to the North Pacific region. The extinct *Enhydra macrodonta* (Kilmer, 1972) is known only from the late Pleistocene. The single surviving species of sea otter, *E. lutris*, dates from the early Pleistocene.

General Factors Contributing to the Vulnerability of Marine Mammals to Extinction

Obligatory Dependence on the Sea Surface for Respiration

Marine mammals must exchange respiratory gasses directly with the atmosphere, in the same manner as their terrestrial relatives. Thus, unlike marine fishes and invertebrates, marine mammals at sea are never entirely free of their association with the sea surface and must return periodically to the surface to breathe. The process of breathing at the surface is often associated with conspicuous activities such as splashing, exhalations audible over long distances, and the production of clearly visible clouds of condensed water vapor associated with exhaled gasses. Marine mammals are often physiologically obligated to remain at the surface for several minutes, allowing multiple exchanges of gas volumes contained in lungs in order to set the biochemical stage for successful subsequent dives. Human travel in watercraft at the sea surface is relatively efficient and advanced. By understanding the respiratory behavior of marine mammals and watching for signs of exhalation, humans in surface watercraft can position themselves to facilitate close contact with surfacing animals. The result is high vulnerability of marine mammals at sea to human hunters.

Large Body Mass and Linear Dimensions

The marine mammals are, on average, large compared with most other animals. The large body size probably evolved in response to certain constraints associated with life at sea, most notably those associated with thermoregulatory and hydrodynamic efficiency, foraging ecology, reproductive ecology and physiology, and habitat preference. The return to the consumer per unit of hunting effort will increase with the mean size of the prey, all other factors being equal. Among the marine mammals, all the mysticetes and many of the odontocetes, pinnipeds, and sirenians are large enough in body mass to be highly desirable as targets by human hunters. With twentieth-century refinements to the technology of marine mammal hunting at sea, pursuit of even the most mobile and dangerous of the marine mammals produced highly desired rates of economic return as long as stocks were not depleted. Thus, large body size, *per se*, increases the vulnerability of marine mammal populations to extinction simply by improving the economic return on investment in hunting activity.

Relatively High Predictability of Spatial and Temporal Distributions in Association with Regions of High Biological Productivity at Sea

With certain exceptions, marine mammals are rarely far removed from locations in which they can forage efficiently. The metabolic generation of heat, fueled by food consumption at high rates, is the only option available to marine mammals at sea for replacing heat lost continuously in a heat-consumptive environment. In species with significant annual migrations to food-poor areas for breeding, high rates of intake during the feeding season are vital for survival of extended travel and fasting as well as for maximizing reproductive fitness. In species whose breeding systems include extensive seasonal fasts, seasonal hyperphagy, requiring proximity to abundant food, may be crucial to reproductive fitness and to long-term survival of both sexes.

Most marine mammals feed on planktonic invertebrates and small schooling fishes and squids. Over the long term, seasonal and spatial patterns of production of zooplankton, forage fish, and squid are relatively predictable. Successful tracking of resources that vary predictability in space and time is vital to survival and reproductive success. Accumulated ecological data for marine mammals indicate that most populations successfully track food resource productivity most of the time. The result is an array of stereotypical seasonal and spatial movements by marine mammals that, in many cases, are readily identified. Clearly, an understanding of movements of marine mammal stocks over time reduces the investment risk in developing strategies for efficient hunting of marine mammals. Thus spatial and temporal predictabilities in marine mammal foraging facilitate efficient hunting by humans and add to the risk of anthropogenic extinction.

Impaired Mobility, Contagious Dispersion, and Temporal and Spatial Predictabilities when Hauled Out on Land

Pinnipeds, the two marine otters, and polar bears are functionally amphibious. Hauling behavior of pinnipeds is particularly synchronous and predictable, producing seasonally dense hauled-out aggregations that can be anticipated readily

in space and time. These patterns are most extreme for some of the land-breeding pinnipeds that dwell at middle or subpolar latitudes, but are prevalent in many other pinniped species as well. Two primary factors contribute to the pattern. First, good hauling sites that are near seasonally predictable foraging locations and are free of the disruptive effects of terrestrial predators such as bears or wolves are typically few in number and small in size. Pinnipeds depending on such hauling sites have evolved high site fidelity and strong navigational capabilities in order to minimize the risk that good hauling sites will be overlooked when needed for breeding, molting, and resting. Second, in the case of pinnipeds at middle and high latitudes, highly productive foraging locations near good hauling sites tend to be strongly seasonal in food availability.

Pinnipeds are awkward on land, and can be captured easily by human hunters on hauling sites, even if methods are primitive. Seasonal hauling patterns are easily recognized in space and time. As a result, human hunters can plan highly efficient hunting of hauled pinnipeds with a low risk of poor return on invested effort. Human activity on preferred hauling grounds can cause significant unintended disruption of breeding activity and social interaction among exploited pinnipeds in addition to directed harvest. The stampeding of panicked animals can lead to premature births, trampling of small pups, permanent separation of mothers from pups, disrupted dominance hierarchies, permanent abandonment of haulouts by adults, and other forms of disturbance. The net added result of hunter-associated disruptions is increased mortality and reduced birth rate in the short term. Repeated disruptions associated with human activity can lead to increased long-term risk of local extinction for populations at particular hauling sites.

Subsistence and Commercial Market Demand for Oil, Blubber, Meat, Baleen, Pelts, and Other Body Parts

By virtue of their frequently large size, morphology, physiology, and chemical composition, the harvested carcasses of marine mammals provide a number of products significant in human subsistence and commercial contexts. Harvested marine mammals provide large quantities of meat, organs, and blubber per unit of hunting effort invested. Meat and organs are used directly for human consumption or to feed domestic animals, such as sled dogs, on which human enterprise may depend. Meat may also be marketed commercially for human consumption or as pet food. Blubber is also consumed directly, but traditionally the majority of blubber is rendered and refined to products such as oil or fuel, used both for subsistence and as commercial commodities. In the case of the odontocetes, oil taken from the organs of acoustic transmission may be refinable to high-quality lubricants that, until recent decades, could not be duplicated synthetically.

Skeletal material from hunted marine mammals has been used traditionally by subsistence cultures for tools, boat construction, dwelling construction, and as raw material for handicrafts and objects of ceremonial significance. Handcrafted articles made from marine mammal skeletons often have significant commercial value as well. Mysticete baleen and the vibrissae of walruses and other pinnipeds have, in the past, been marketed commercially as components of clothing or personal toilet articles, although such uses are largely in the

past. Hides and pelts may be used for clothing and for construction of boats or dwellings. The pelts of sea otters and fur seals have been sought for centuries as commodities of high commercial value for clothing, or as adornments for ceremonial robes and artifacts. Teeth and other body parts from sea otters are also known to have had ceremonial significance to indigenous peoples. Polar bears and walruses have been hunted for meat, oil, hides, and pelts by subsistence cultures for millennia, and have been targets of trophy hunters since the nineteenth century, particularly since the development of modern firearms as tools for hunting.

Much of the demand for marine mammal products centers on tissues involved in thermoregulation. The blubber of cetaceans, pinnipeds, and sirenians, and the pelts of fur seals, sea otters, and polar bears are the respective primary organs of heat retention, allowing the preservation of homeothermy in a chilling environment. Thus the homeothermic physiology of marine mammals underlies their desirability as commodities, and is a significant contributor to vulnerability of marine mammals to anthropogenic extinctions.

Low Demographic Potential for Rapid Recovery from Disturbance or Overexploitation

The marine mammals are significantly convergent in many aspects of life history. Mean litter size is one for all species, except polar bears and chungungos, and multiple births are quite rare in cetaceans, pinnipeds, sirenians, and sea otters. The age of first reproduction is often relatively high, especially in sirenians and the larger odontocetes. None of the extant marine mammals has a birth interval of less than one year, and for many species the birth interval is at least several years. In all species, parental care is entirely maternal, and the energetic costs of lactation and other forms of care are extensive for the adult female. Reproductive success of newly mature females is often low in marine mammals, increasing only with experience. Survival rates of weaned offspring may be low during the first few years of independence.

The combined effects of the above characteristics are low potential rates of growth in marine mammal populations, even when constraints of food limitation, competition, predation, or natural disturbance are alleviated. Maximum potential annual rates of population growth typically are 2–4% for the cetaceans and sirenians and 10–12% for the pinnipeds and sea otters. Exceptional cases, both higher and lower than mean rates, are known for both groups. Realized rates of growth, affected by variations in food supply and the effects of disturbance, predation, competition, and possibly other factors, often are much closer to zero and at times may reach negative values. Given these patterns, recovery from depletion associated with excessive exploitation or disturbance may require many years, and intervening additional harvest or disturbance may raise the risk of extinction to irreversible levels.

Morphological, Physiological, and Ecological Predisposition for Bioaccumulation of Lipophilic Anthropogenic Contaminants and Toxins

Most marine mammals utilize a well-developed subcutaneous blubber layer as the primary means of thermoregulation. The lipid-based blubber layer is also a primary organ for energy storage, as are fat deposits in polar bears. Many species of

cetaceans and pinnipeds, the Amazonian manatee, and some polar bears have an extensive seasonal fast each year, relating to migration away from primary feeding areas, an extended haul-out or denning period in association with reproductive activity, or shifts in habitat structure. During such fasts a significant proportion of the blubber layer or fat deposits is metabolically mobilized to meet energy and water demands during the fasting period. Following the fast, animals return to the feeding grounds and forage intensively to reconstitute the reduced blubber layer or fat deposits. In the case of the odontocete cetaceans, the acoustic melon is a second concentration of lipid-based tissue.

Odontocetes, pinnipeds, the two marine otters, and polar bears occupy high trophic levels in marine food webs. Many stable lipophilic contaminants are transmitted through food webs, such that top-level consumers may be exposed to high levels of contaminants. Such patterns are particularly well known for environmental contaminants such as organochlorines, a group including the polychlorinated biphenyls (PCBs) and the various derivatives of dichlorodiphenyltrichloroethane (DDT), and the polybrominated diphenyl ethers (PBDEs). In this context, many marine mammals face the double jeopardy of a high position in their respective food webs and, thus, the risk of high exposure to stable lipophilic contaminants, and extensive, metabolically active lipid-based tissues vital to survival, but vulnerable as sites for accumulation of contaminants. Some scientists question the demographic significance of contaminants to marine mammals, noting the relatively small number of cases of quantitative linkage of contaminant levels to alterations of population dynamics. However, in several cases, lipophilic contaminants have been correlated with reduced immune competence, disease outbreaks, and significant mass mortalities in marine mammal populations. There is also evidence that contaminants may cause endocrine disruption and reproductive malfunctions such as premature deliveries of pups. Thus, the combination of lipophilic contaminants in the marine environment, the pattern of foraging at high trophic levels by marine mammals, and the metabolically active lipid-based tissues present in many marine mammals result in increased vulnerability of marine mammals to anthropogenic extinction.

Overlap of Diet or Habitat with Commercial or Recreational Fisheries

Marine mammals often feed preferentially on prey species also sought by commercial, recreational, or subsistence fisheries, or forage in habitats in which significant commercial fishing activity occurs. These patterns create two types of problems that may enhance the vulnerability of marine mammals to anthropogenic extinction. In the first case, marine mammal populations are viewed by commercial, recreational, or subsistence fishers as competitors for a common resource. As a consequence, legal recourse may be sought to actively reduce the range or numbers of marine mammals by killing, translocation, or harassment in order to reduce the intensity of competition in favor of harvesting interests. Illegal activities may also result, including unauthorized killing or harassment intended to reduce the intensity of competition between marine mammal populations and fisheries. Such circumstances

can lead to conflicting management goals by interested parties, particularly if the involved marine mammal populations are small. From the perspective of the involved marine mammal species, competition from harvesting interests may alter the quantity or distribution of food availability and may produce significant consequences at the population level.

The second type of problem is inadvertent or incidental take of marine mammals by entanglement in fishing gear. Such taking may include injury or death of individual animals, possibly producing significant effects at the population level. Potential solutions to such problems include tolerance of taking by management authority, changes to fishing techniques or effort to reduce rates of taking, or displacement of fishing effort to other locations. Such interactions may still result in population-level effects if reduction in rates of taking is inadequate or if parties affected by displacement of fishing effort resort to illegal taking of involved marine mammals as a form of retribution. Thus both types of problems may contribute to increased risks of extinction.

General Factors Hindering Effective Identification and Monitoring of Marine Mammal Populations Vulnerable to Extinction

Availability Bias

Marine mammals at sea spend most of their time below the sea surface. Depending on water clarity, typical depth of dive, angle of observation, and platform of observation (i.e., surface vessel or aircraft), a varying proportion of individual marine mammals in a field of view cannot be seen, and thus cannot be enumerated, in a population survey (e.g., [Garner et al., 1999](#)). The proportion of animals not visible because of submergence is the availability bias of the survey. Availability bias reduces both accuracy and precision of population estimates, and reduces the statistical power of a survey effort to detect population trends correctly. Availability bias can be estimated with detailed information on water clarity in the survey area, diving characteristics of target species, and detection characteristics of survey observers. Estimates of bias allow the effects of the bias to be incorporated into calculations of coefficients of variation (CVs) for population estimates. Elimination of availability bias generally is not possible for surveys at sea.

Availability bias may also be a problem for surveys directed to hauled animals on shore. For example, topographic irregularities such as rocky overhangs may obscure animals that are present in the defined survey area, and animals at high density may obscure one another. Judicious timing and modified survey angles may sometimes reduce availability bias in surveys of hauled animals to nearly zero.

Observer Bias

Observer bias, also known as detection bias, results from the inability of survey observers to correctly enumerate the number of animals visible in a field of view. Like availability bias, observer bias typically is a low bias. That is, observers typically fail to see and count all animals that are present in a field of view. Observer bias has the same implications for population estimation as summarized above for availability bias. Observer

bias can be a significant source of error in both surveys at sea and surveys of hauled animals on shore. Observer bias can be reduced with increased experience of individual observers, and can be estimated using double-counting techniques with paired independent observers or by comparing observer counts in the field with counts from aerial photographs taken at the same time and place.

An important form of observer bias involves errors in estimates of group size in marine mammal surveys. Typically, marine mammal surveys involve counting of groups in the survey area. The group count is then multiplied by the mean group size, often based on a separate survey effort, as the first step in population estimation for the survey area. However, estimates of group size are themselves subject to observer bias, contributing to an increase in the CV for population estimates. Observer bias in group size estimates can be assessed under good conditions by comparing group size counts by observers with group size counts based on aerial photographs of the same group of animals taken during the surveys.

Low Statistical Power of Population Survey Data to Detect Trends in Population Size

In many cases the single most important type of information for assessing the status of a marine mammal population is the trend in population size over time. A trend is simply a time series of counts in which the slope of a fitted line is significantly different from zero. In a statistical context, the ability to detect a trend correctly is influenced by four factors. The first is the strength of the trend. Strong trends are those in which the absolute value of the slope of the fitted line is large. When other factors are constant, strong trends are more likely to be detected correctly than weak trends. The second factor is estimation error. Other factors being equal, trends in survey-based estimates of population size over time are more likely to be detected correctly if the associated CV is small than if it is large. The third factor is the number of replicate surveys available for a given time period, to be used to calculate a single estimate of population size. The probability of correctly detecting a trend increases with the number of replicate surveys used to calculate each point in the population time series, other factors being equal. The fourth factor is the number of years in which surveys are done. The probability of correctly detecting a trend, with other factors equal, is increased with an increasing number of survey years.

Many marine mammal surveys have characteristics that reduce the probability of correctly detecting trends. Weak trends may portend significant conservation concerns for marine mammals, but are inherently difficult to detect if CVs are large and replication minimal. Large CVs are common in all types of marine mammal population surveys, although CVs are gradually being reduced by the efforts of involved researchers and managers. The level of replication generally is directly dependent on levels of funding. Funding for field surveys in marine mammal science is often compromised by the challenge of limited legislative appropriations and competing priorities. Well-executed marine mammal population survey programs generally detect strong population trends successfully. However, many surveys lack the statistical power to detect weak trends that may nevertheless be important in the context of avoiding eventual extinction of marine mammal

populations. The only solution is to extend survey effort over a number of years, thus improving the odds of recognizing a trend. Such an approach carries the obvious risk of potentially delaying the recognition of a significant conservation problem for the target population, and inevitably increases the overall monetary cost of the monitoring effort. In many cases there is no methodological alternative to extending the time scale of the monitoring effort.

Inadequate Understanding of Vital Demographic Parameters

Determination of effective measures to eliminate a negative trend in a marine mammal population often depends on a reasonable understanding of the demographic characteristics of the subject population. Such an understanding improves the odds that limited resources for conservation work will be applied where the greatest benefits will accrue. The demographic parameters of marine mammal populations often are known only with poor levels of accuracy or precision. In such cases, conservation effort can be readily misdirected. For example, measures to reduce preweaning mortality in a marine mammal population will be ineffective if the larger problem is a high rate of adult female mortality obscured by imprecise or inaccurate estimates of adult female survival rate. Misdirection of limited resources for conservation has obvious effects on extinction probabilities for populations in jeopardy.

Accurate, precise measurements of population parameters in marine mammals are difficult to obtain. In all marine mammal species, the time line necessary to obtain good parameter estimates is lengthy, and the best data come from studies that extend beyond a decade in duration. One of the important results of long-term demographic research on marine mammals is evidence, in some cases, of marked interannual variability in demographic parameters, further emphasizing the critical need for a long time scale in such studies. For many species good estimates of demographic parameters require tagging of individuals, an invasive process that can impose risks of reduced survival for the tagged individual and risks of disturbance to groups of animals such as pinniped breeding colonies on haulouts. In some cases, tagging has the potential to bias the demographic data recorded from the tagged individual. Finally, because of the lengthy duration and labor intensity involved, demographic studies may be quite costly and therefore difficult to implement.

Inadequate Understanding of Effects of Environmental Uncertainty on Dynamics of Populations

There is limited evidence that apparently stochastic environmental fluctuations may have important effects on the dynamics of marine mammal populations. The best-known cases involve the pinnipeds, primarily because pinnipeds breed on solid substrata and therefore have more readily observed and better-known population dynamics than most other marine mammal taxa. For example, during 1982–1983 and 1997–1998, food supplies for many temperate pinniped populations in the North Pacific were disrupted by global-scale oceanographic disturbances generally known as “El Niño – Southern Oscillation” (ENSO) events. ENSO events involve a suite of changes in global wind and ocean current patterns, with major large-scale effects on patterns of biological

productivity. Although often drastic, local changes in productivity typically are temporary, returning to normal levels over time periods from a few months to a few years. ENSO events have stochastic characteristics regarding both the frequency and the intensity of occurrence, and may be stochastic in their effects on survival rate and population trajectory of marine mammals. Both of the referenced ENSO events caused significant reduction in some pinniped population sizes, and increased rates of mortality in pups of the year. In the context of extinction, the major problem in incorporating naturally occurring stochastic events into conservation planning is the lack of good-quality data from an adequate number of events. Thus, it is not possible to generalize about effects of stochastic events, nor is it possible to reasonably consider mitigation measures to minimize increased extinction risks associated with stochastic events.

High Cost of Survey Efforts

Despite their obvious conservation value, survey efforts for marine mammal populations often are compromised or eliminated by funding constraints. The central problem is the high cost per unit effort of a good-quality survey for marine mammals at sea. Most surveys at sea use either aircraft or large surface vessels as platforms for observation. Both types of platforms are costly to operate at the level of rigor and safety necessary to obtain statistically defensible estimates of target population size. The monetary costs of good at-sea surveys may be a significant proportion of the research and management budgets of resource-oriented government agencies, even in wealthy countries such as the US. In most cases, low-cost alternatives simply do not exist. As a consequence, only the most serious issues of population trend in marine mammal conservation can reasonably attract a quantitatively rigorous level of survey effort. Thus, funding realities improve the risks of extinction by improving the odds that trends of concern will be overlooked for lack of the necessary survey effort.

Lack of Consensus and Consistency in Definition of Objective Criteria for Determination that Particular Populations are Vulnerable

There are many forms of institutional or organizational protocols designed to provide protection for depleted populations of wildlife, including marine mammals. Many such protocols originate from and have the backing of government agencies. However, few protocols for the protection of species in peril include explicit, objective criteria for determining the level of jeopardy, or for specifying recovery from jeopardy status. Moreover, those cases in which objective criteria are specified rarely accommodate the quantitative uncertainties in population estimation, demographic parameterization, characteristics of ecological disturbance, and related issues that are universal problems in population data for depleted wildlife. Surveys of criteria for status determination of wildlife in peril reveal little consistency, and often only minimal consideration of fundamental biological patterns, even within particular political jurisdictions.

Resolution of the problem of objective criteria is difficult. Different taxa of organisms have different population characteristics, and may warrant different approaches to the development of objective criteria for jeopardy and recovery. Differences in culture, values, and political traditions among

jurisdictions also complicate any effort to establish common objective criteria. However, the separation of jeopardy criteria from arbitrary judgments, often intertwined with political considerations, is crucial to ensure that extinction risk is measured by biological criteria. A failure to achieve such separation may increase the odds of extinction for some populations in peril.

Problems in Distinguishing “Natural” from “Unnatural” Extinction

As indicated above, marine mammals have been present on earth since the early Eocene. The majority of the marine mammals that have evolved on earth are now extinct, and virtually all extinctions occurred before the evolution of the hominid primates, and particularly *Homo sapiens* (Linnaeus, 1758). In the context of conserving the earth’s biodiversity, however, we are primarily concerned about anthropogenic loss of species. Thus, excepting material in our section Extinction or Near Extinction of Major Taxa Over Evolutionary Time (below), our time window is narrowed to the Pliocene, Pleistocene, and Holocene, and our conceptual focus to extinctions that result from conscious human action rather than from other, “natural” processes such as changing habitat, disturbance and catastrophe, or displacement of one species by another. We suggest that not all anthropogenic extinctions are necessarily “unnatural”. However, separating the “natural” from the more philosophically distasteful “unnatural” is a great challenge, much burdened by the complicating considerations of values, culture, politics, and economics. Thus, the distinction, however important, is well beyond the scope of our contribution.

Patterns and Case Studies of Extinction in Marine Mammals

In this section, and particularly in sections Modern Anthropogenic Extinctions of Species, Subspecies, and Major Populations through Species, Subspecies, or Populations Once Thought to be Near Extinction, Now Showing Evidence of Increasing Numbers, we review case studies of taxa in varying degrees of peril with regard to extinction. It is not our intent to be 100% comprehensive with regard to taxa in jeopardy. Rather, our intent is to provide examples in sufficient number to illustrate the full range of factors that influence extinction risk on a global scale. In addition, geographic bias will be apparent in the cases we present. The bias results primarily from the geographic tendencies of our respective research experience and from our relatively greater familiarity with marine mammal conservation issues in the northern hemisphere, and in particular with cases from coastal regions of North America.

Extinction or Near Extinction of Major Taxa Over Evolutionary Time

Odobenidae

The odobenids have a fossil record of striking diversity, including some species resembling modern walruses and others

superficially similar to the modern sea lions and fur seals. All known odobenid fossils have been found in the northern hemisphere. The odobenids seem to have diverged from the otariids in the early Miocene. Peak fossil diversity is in strata from the late Miocene and early Pliocene. Diversity declined abruptly during the late Pliocene and Pleistocene. The single surviving species, the modern walrus, appeared in the fossil record during the Pleistocene. Extinct odobenids were also broadly distributed across latitude. The modern walrus is limited to high northern latitudes and is distributed aberrantly relative to the extinct odobenids.

The fossil record indicates that modern walruses are the single relict of a largely lost taxon. Most extinctions of odobenids seem to be associated with global-scale cooling and related large-scale habitat change during the Pliocene. However, ecological characteristics of the extinct odobenids are in many cases difficult to understand because the surviving contemporary model seems aberrant. Thus, it is difficult to develop meaningful functional models of extinction in the odobenids.

Sirenia

Sirenian diversity clearly peaked during the Miocene, a period of warm global climate coincident with extensive warm shallow coastal marine habitats. The dugongids, now represented by a single surviving species, were the most diverse family of sirenians through the fossil record. Sirenian diversity declined sharply during the relatively cool Pliocene and Pleistocene, and modern forms are relicts of a largely extinct order. Two of four recognized sirenian families are now fully extinct.

Unlike the odobenids, the surviving sirenians seem to provide good ecological models for the extinct forms. Modern sirenians typically consume macrophytes in shallow waters and clearly prefer warm protected waters. Thus, it is likely that Pliocene cooling and the coincident widespread loss of warm shallow seas were major factors in the decline of the sirenia. Surviving species were those able to retreat to low-latitude refugia or, in the case of the Steller's sea cow, a subpolar refuge with abundant food and apparently with no significant predators.

Desmostylia

Desmostylians did not diversify to nearly the extent of the other major marine mammal taxa, and did not survive beyond the end of the Miocene. Lacking modern ecological models, we prefer not to speculate on specific ecological mechanisms of extinction in the desmostylians. However, loss of the taxon coincided in time with the decline of sirenians, with which desmostylians share common ancestry. Thus habitat needs and associations may have been similar between late Miocene sirenians and desmostylians, and loss of optimal habitats during Pliocene cooling could have had similar effects on both groups.

Modern Anthropogenic Extinctions of Species, Subspecies, and Major Populations

Species Level

Following the taxonomic format of Rice (1998), four species of Holocene marine mammals are known to be extinct. In all

cases the probable causes were anthropogenic. In addition, Rice (1998) reports anecdotal evidence from non-technical sources that a recent species of pinniped, undescribed and entirely unknown to science, once occurred in the Chagos Archipelago and Seychelles Islands of the tropical southwestern Indian Ocean. If such a species occurred it is now extinct as a result of unknown factors.

*Baiji (Yangtze River Dolphin): *Lipotes vexillifer* Miller, 1918*

The baiji, also known as the Yangtze River dolphin or Chinese River dolphin, was the sole known member of the family lipotidae. The baiji dwelled exclusively in fresh water habitats of the middle and lower Yangtze River (from Yichang eastward to the river mouth at Shanghai) and the adjacent Qiantang River in southeastern China. Accounts of population surveys are summarized by Turvey *et al.* (2007). The baiji had been recognized as imperiled for a number of decades. Baiji were not seen in the Qiantang River after the 1950s. Surveys of baiji habitat in the Yangtze River in the late 1970s suggested a population of 400 individuals. By the middle 1990s population estimates were less than 100 animals. The last authenticated observation of a live free-ranging baiji was in 2002. Turvey *et al.* reported the results of a combined intensive survey of the entire known range of the species in 2006 using multiple vessels and visual and acoustic survey methods. No animals were located and the baiji appears to be extinct in all known native habitats. There are no living baiji in captivity. Likely causes for the loss of the baiji include high rates of bycatch in fishing gear, erosion of environmental quality due to dam construction and industrial pollution, and shipstrikes. Turvey *et al.* suggest that fishery bycatch was the predominant risk factor contributing to apparent extinction. Bycatch intensity probably correlated directly with the extreme density of the human populations, and associated high demand for dietary protein, in the Yangtze watershed. The region was home to roughly 650 million people at the time of the baiji survey in 2006, approximately 10% of the earth's human population. The intensive industrialization of the Yangtze region, and the obviously diminished air and water quality characteristic of the area, likely contributed to loss of the baiji as well.

*Caribbean Monk Seal: *Monachus tropicalis* (Gray, 1850)*

The Caribbean monk seal was one of three recent species of *Monachus*. All occur or occurred in tropical or subtropical latitudes. The pre-exploitation range of *M. tropicalis* included the islands of the Caribbean Sea, the coastal regions of Venezuela and Caribbean Colombia, southern Florida, the east coast of Mexico south of the Bay of Campeche, and the Caribbean coasts of Belize, Guatemala, Honduras, Nicaragua, Costa Rica, and Panama. Estimates of pre-exploitation population sizes are not available. Intensive hunting of seals for meat and oil began soon after arrival of European explorers in the late fifteenth century. Seal populations were reported as depleted as early as the seventeenth century, but a few animals survived into the middle twentieth century. The last confirmed sighting of a Caribbean monk seal was at Seranilla Bank, west of Jamaica, in 1952. Directed surveys for seals in the later 1950s and 1960s found no living animals.

Japanese Sea Lion: Zalophus japonicus (Peters, 1866)

The Japanese sea lion is sometimes considered a subspecies (*Zalophus californianus japonicus*) of the California sea lion. Here we follow the convention of Rice (1998) in regarding the sea lion as a separate species. The Japanese sea lion originally ranged along the shores of Japan and Korea, and the southern Pacific shores of Russia. The species was subject to a long history of hunting for meat and oil. No population surveys were done. The sea lion was thought to be extinct at the end of the nineteenth century, but a group of animals was reported from the Takeshima Islands in 1951. There have been no subsequent sightings and the species is now considered extinct.

Steller's Sea Cow: Hydrodamalis gigas (Zimmerman, 1780)

Steller's sea cow was first observed by a scientist in 1741, at which time it occurred only along the shorelines of the Komandorskiye Ostrova, east of the Kamchatka Peninsula of Russia. At the time of discovery, sea cows probably numbered no more than a few thousand individuals in total, but population surveys were not done. There are reports that the sea cow had previously occurred along the eastern shore of mainland Kamchatka and in the Near Islands of the Aleutian Archipelago, but the primary evidence is material from stranded carcasses that could have resulted from long-distance drift at sea. Sea cows were subject to intensive hunting, soon after discovery, by crews of sea otter hunters working in the Komandorskiye and Aleutian Islands. Sea cows provided high-quality meat and blubber in great quantity and facilitated extended harvesting expeditions by otter hunters. The last sea cow observation was recorded in the Komandorskiye Ostrova in 1767. The only scientific observations of living Steller's sea cows were made by G.W. Steller at Bering Island in the Komandorskiye Ostrova. Steller recorded his observations under extremely difficult conditions while stranded during the winter of 1741–1742, following the shipwreck of the *Saint Peter*, one of two vessels comprising the Bering Expedition from Kamchatka to southern Alaska.

Three factors probably contributed to the extinction of Steller's sea cow. First, directed hunting was intensive and unmanaged. Second, at the time living sea cows were observed by Steller, they occurred only on islands lacking aboriginal human populations. The pattern suggests that aboriginal hunters may have previously reduced the range and numbers of sea cows, predisposing them to extinction when hunting intensified. Third, sea cows foraged on near-shore benthic kelps and other macroalgae. The rapid depletion of sea otter populations by otter hunters in the Komandorskiye Ostrova may have allowed sea urchins, the primary prey of otters in the region, to overgraze their preferred food, the same kelps utilized by sea cows. Thus, catastrophic loss of food supply could have facilitated the rapid extinction of sea cows.

*Subspecies or Population Level**North Atlantic Gray Whale: Eschrichtius robustus (Lilljeborg, 1861)*

Whaling records and subfossil remains indicate that a population or populations of gray whales (*E. robustus*), apparently not taxonomically distinct from North Pacific populations, once occurred along both coasts of the North Atlantic.

Available evidence suggests that gray whales occurred along the Atlantic coast of North America into the seventeenth century but probably not beyond. There are no available data on population size, foraging or breeding habitats, or migratory corridors, nor is there evidence bearing on the question of genetic relatedness between gray whales off western Europe and those off eastern North America. Subfossil specimens have been found in Europe from the central Baltic coast of Sweden to Cornwall in the UK, and in North America along the US east coast from New York to South Carolina. Confirmed sightings of a single gray whale in the Mediterranean Sea in spring 2010, off Israel and Spain, are considered to be the result of navigation errors by a whale from the eastern North Pacific population, facilitated by opening of new travel corridors due to climate-based loss of sea ice cover in high northern latitudes. The most likely explanation for extinction of North Atlantic gray whale populations is prolonged excessive harvest by the whaling industry.

Species, Subspecies, and Populations in Imminent Peril of Extinction**Synopsis**

Here we summarize the status of 26 marine mammal taxa or populations that in our view face a substantial probability of extinction during the twenty-first century (Table 3).

We provide more detailed information for five case studies of populations in this category. In all but one of the 26 cases, available data suggest total abundances of less than 1000 individuals. Most of the taxa or populations considered in this category have several significant past or current anthropogenic sources of mortality that facilitate extinction risk. In nearly all cases, the scope of operational resource investment and human societal adjustment necessary to avoid extinction is high. The recently reported extinction of the Yangtze River dolphin (see Baiji (Yangtze river dolphin): *Lipotes vexillifer* Miller, 1918) represents a case in point.

North Pacific and North Atlantic Populations of the Right Whale: *Balaena glacialis* Müller, 1776

Right whales occur in three major regions, the North Pacific, the North Atlantic, and the Antarctic Ocean, together with adjoining regions of the South Pacific, South Atlantic, and South Indian Oceans. Because of intervening land masses and the antitropical distribution of the species, rates of migration and genetic exchange among the three regions are low. The primary conservation problem for the northern populations is small population sizes, imposed largely by centuries of unregulated commercial and subsistence whaling, from which recovery has not occurred. Rice (1998) considers all populations of right whales to be a single species, *B. glacialis*. Although we follow Rice's systematic treatise in this article, we note that most specialists divide right whales into more than one species. The more commonly supported protocol classifies North Pacific right whale populations as *Eubalaena japonica* (Lacépède, 1818), North Atlantic right whales as *Eubalaena glacialis*, and southern hemisphere right whales as *Eubalaena australis* (Desmoulins, 1822).

Right whales were identified by the earliest whalers as targets of choice because of their abundance, large size, high

Table 3 Species, subspecies, or populations thought to be in imminent peril of extinction

<i>Taxon</i>	<i>Population</i>	<i>Estimated population size^a</i>	<i>Current and historical risk factors</i>
North Pacific right whale: <i>B. glacialis</i> Müller, 1776 ^b	Eastern North Pacific	30	CH, ISW, ITF, LRN, VC
North Pacific right whale: <i>B. glacialis</i> Müller, 1776 ^b	Western North Pacific	Unknown but small	CH, ITF, LRN, VC
North Atlantic right whale: <i>B. glacialis</i> Müller, 1776 ^b	Eastern North Atlantic	A few animals, possibly extinct	CH, ITF, LRN, VC
North Atlantic right whale: <i>B. glacialis</i> Müller, 1776 ^b	Western North Atlantic	360	CH, ITF, LRN, VC
Southern right whale: <i>B. glacialis</i> Müller, 1776 ^c	Chile and Peru	A few animals	CH, ITF, LRN, VC
Bowhead whale: <i>B. mysticetus</i> Linnaeus, 1758	Davis Strait and Baffin Bay	450	CH, LRN, OW
Bowhead whale: <i>B. mysticetus</i> Linnaeus, 1758	Svalbard, Barents Sea	A few animals, possibly extinct	CH, LRN
Bowhead whale: <i>B. mysticetus</i> Linnaeus, 1758	Sea of Okhotsk	A few hundred	CH, LRN, OW
Gray whale: <i>E. robustus</i> (Lilljeborg, 1861)	Western North Pacific	130	BSR, CH, ITF, LRN, MO, VN, VC
Humpback whale: <i>M. novaeangliae</i> (Borowski, 1781)	Arabian Sea	A few hundred	ISW, ITF, LRN
Vaquita: <i>P. sinus</i> Norris and McFarland, 1958	Northern Golfo de California	500–600	ITF, LRN
North Island Hector's dolphin: <i>Cephalorhynchus hectori maui</i> (Baker <i>et al.</i> , 2002)	North Island, New Zealand	120	CP, DIS, HLP, ITF, LRN VC, VS
Pacific humpback dolphin: <i>Sousa chinensis</i> (Osbeck, 1765)	Eastern Taiwan Strait	100	CP, ITF, LR, LRN
Killer whale: <i>O. orca</i> (Linnaeus, 1758)	Southern resident population (Washington, USA, and British Columbia, Canada)	90–100	CFP, CP, DT, LCR, LRN, VN
Beluga whale: <i>D. leucas</i> (Pallas, 1776)	Cook Inlet & Northern Gulf of Alaska	340	CH, CP, LRN, OW, SH
Beluga whale: <i>D. leucas</i> (Pallas, 1776)	Ungava Bay, Canada	A few animals	CH, CP, LRN, OW, SH
Indian river dolphin: <i>Platanista gangetica</i> (Roxburgh, 1801)	Ganges, Indus, Brahmaputra, and Karnaphuli Rivers	Unknown	CP, DD, HLP, ITF, LRN, SH, TAM
La Plata dolphin: <i>Pontoporia blainvillei</i> (Gervais and d'Orbigny, 1844)	Uruguay and Rio Grande del Sul, Brazil	300	CFP, CH, HLP, LRN, ITF, MDI
Harbor porpoise: <i>Phocoena phocoena</i> (Linnaeus, 1758)	Black Sea and Aegean Sea	Unknown	CP, CH, DIS, LRN, MO, TAM
Harbor porpoise: <i>Phocoena phocoena</i> (Linnaeus, 1758)	Northern Baltic Sea	600	CH, CP, ITF, LRN
Northern bottlenose whale: <i>Hyperoodon ampullatus</i> (Forster, 1770)	Scotian Shelf, particularly the "Gully" submarine canyon	160	CH, CP, LRN, VN
Mediterranean monk seal: <i>M. monachus</i> (Hermann, 1779)	Eastern Mediterranean Sea, northwestern Africa, and Madeira	350–450	CFP, CP, DHD, LRN, PO, SH
Hawaiian monk seal: <i>Monachus schauinslandi</i> Matschie, 1905	Hawaiian Islands west to Kure Atoll	Approximately 1000	FLI, HOF, ITF, LRN, PR
Lake Saimaa ringed seal: <i>P. hispida saimensis</i> (Nordquist, 1899)	Lake Saimaa, Finland	270	ITF, LRN, OW
Ungava seal: <i>Phoca vitulina mellonae</i> Doult, 1942	Ungava Peninsula, Québec, Canada	100–600	LRN
Chungungo: <i>Lutra felina</i> (Molina, 1782)	All	Less than 1000	CH, CP, IHC, ITF, LCR, PO

^aIndicated estimates of population size reflect a wide range of quantitative rigor. Primary sources for estimates shown are online resources associated with NMFS, FWS, and RLTS. The responsibility for errors rests exclusively with the authors of this article.

^bSome taxonomists consider the North Pacific right whale a separate species, *Balaena japonica* (Lacépède, 1818). Here we follow the convention of Rice (1998), regarding the North Pacific and North Atlantic right whales as one species.

^cSome taxonomists consider the southern right whale a separate species, *Balaena australis* (Desmoulin, 1822). Here we follow the convention of Rice (1998), regarding the North Pacific and North Atlantic right whales as one species.

Codes for risk factors are as follows (codes also apply in Tables 4 and 5): BSR, biased sex ratio; CFP, competition with fisheries for prey; CH, commercial harvest; CP, contaminants and pollution; DD, dams and diversions; DHD, deliberate habitat destruction; DIS, diseases; DT, disturbance by tourism activities; FLI, food limitation from oceanographic anomalies; HLP, habitat loss for prey; HOF, haulout flooding from sea level rise; IHC, illegal harvest to reduce competition for prey with fisheries; ISW, illegal Soviet whaling; ITF, incidental take in fisheries; LCR, live-capture harvest; LR, land reclamation; LRN, limited range or low numbers; MDI, marine debris ingestion or entanglement; MO, marine oil/gas exploration, production, or transportation; OW, ocean warming and sea ice reduction; PO, poaching; PR, predators; SH, subsistence harvest; TAM, terrestrial agriculture, mining, deforestation, and urbanization; VC, vessel collisions; VN, vessel noise.

yields of meat and blubber, relatively docile behavior, and relative buoyancy *post mortem*. Historical records suggest that significant exploitation of the North Atlantic populations began along the European coast early in the second millennium AD. Changes in hunting effort over time and space followed the stereotypical pattern of overexploitation. As coastal European stocks of whales were depleted, whalers expanded efforts westward to Greenland, Newfoundland, and Labrador beginning in the sixteenth century. Subsequent stock depletion led to further expansion of harvest effort southward in the seventeenth century to the waters of what are now Nova Scotia, and the US right whale populations off the northeastern US were depleted after the middle eighteenth century and may have numbered as few as 20 individuals. The historical record of right whale harvest is less lengthy for the North Pacific, but almost certainly followed the same general pattern. Commercial whaling was most intensive in the nineteenth century. Recovery of North Pacific right whales during the twentieth century was damaged by substantial illegal harvest by whalers from the USSR during the 1960s. North Atlantic, North Pacific, and southern hemisphere right whales are listed as “endangered” throughout their respective geographic ranges, pursuant to the US Endangered Species Act (ESA) of 1973 (16 USC §§1531–44) as amended (ESA). The Red List of Threatened Species (RLTS), managed by the International Union for the Conservation of Nature, shows North Atlantic and western North Pacific right whale populations as “endangered” and the eastern North Pacific population as “critically endangered”.

Between 360 and 400 individual right whales are thought to be present currently in the North Atlantic. The eastern population, off the coast of Europe, probably contains only a few individuals and is in extreme jeopardy of extinction. It is possible that the eastern population is effectively extinct, and that right whales occasionally seen in the region are strays from the western population. The western population ranges along the coast of Canada and the US and is thought to contain at least 360 individuals. During the twentieth century, estimated annual growth rates of the western population never exceeded 2.5%. The two populations recognized in the North Pacific are also quite small. The western population, ranging from the western Bering Sea to southern Japan, is thought to be somewhat larger than the eastern population, which ranges from the eastern Bering Sea to southern Baja California, Mexico. The eastern population numbers approximately 30 individuals and may have suffered irreparable damage from the illegal Soviet whaling noted above. An estimate of trend in numbers in the eastern population has not been made. The eastern North Pacific right whale population is almost certainly the most critically endangered of the world’s large whale populations for which population size estimates are available.

Failure of northern right whale populations to recover from the cessation of commercial whaling has been difficult to understand, except the obvious damage from illegal whaling in the North Pacific in the twentieth century. Southern right whale populations protected from exploitation have grown at rates estimated as high as 6–7% per year, and there is no evidence of major differences in genetically defined vital rates between northern and southern populations. Thus, other factors must be retarding population growth in the north. Northern

populations of right whales tend to be concentrated in regions that support productive and highly capitalized fisheries, facilitating damaging rates of incidental entanglement. Right whales are also concentrated in areas frequently transited by large ships, facilitating lethal ship strikes. Vulnerability to shipstrikes is enhanced by the apparent tendency of right whales to rest quietly at the surface for long periods, in a manner minimizing the probability of detection by vessel operators. Survival of northern right whale populations beyond the twenty-first century requires continued prohibition of all forms of directed harvest and the largest possible reductions in rates of incidental taking and shipstrikes. Eastern populations in the North Atlantic and North Pacific may be destined for extinction within the century regardless of actions taken.

Western North Pacific Gray Whale: E. robustus (Lilljeborg, 1861)

The western North Pacific population of gray whales probably originally summered in the Sea of Okhotsk, and migrated south to winter habitats in southern China. Focused ecological studies of the population have been done only within the last two decades. The western gray whale population is among the smallest of large whale populations in the world and, as with the eastern North Pacific right whale, is highly vulnerable to extinction in the twenty-first century. The principal conservation concerns for western gray whales are the small population size resulting from commercial whaling in previous decades, incidental take in Japanese net fisheries during migration, a significant male bias in population sex ratio, a lack of knowledge regarding migratory corridors and destinations, and risks posed by offshore oil development in the current summer feeding range of the population. The western gray whale population is listed as “endangered” as per ESA, and “critically endangered” as per RLTS.

Western gray whales forage on benthic invertebrates during summer months in shallow coastal waters off northeastern Sakhalin Island, Russia. Foraging activity is particularly intensive in a small near-shore area off the entrance channel to a large coastal lagoon, Zaliv Pil’tun (52°50’ N, 143°20’ E). Data from photoidentification studies indicate high fidelity of foraging gray whales to the area off northeastern Sakhalin, particularly near Zaliv Pil’tun, within and among years since 1995. Adult females with calves show particularly high fidelity to the feeding area near Zaliv Pil’tun, suggesting that the area is important to calf rearing. In recent years, small numbers of western gray whales have been observed during summer at near-shore locations in the southwestern Bering Sea.

Previous estimates of the western gray whale population, based on minimal data, were in the range of 200–300 individuals. Intensive recent studies have focused on photographic identification of individual whales, exploiting individual-specific markings on the skin. Application of population models to the photoidentification data suggests a current population size of approximately 130 individuals. The photoidentification data coupled with other direct field observations also indicate a significant male bias in sex ratio (male:female ratio ~0.65) for unknown causes. The bias in sex ratio influences effective population size and could reduce the growth potential of the population.

Six gray whales have been reported killed by entanglement in Japanese fishing gear, and a seventh in Chinese fishing gear, with five of the events occurring since 1995. Most entanglements involve a type of set net known among Japanese fishers as the "fixed shore net." It is likely that the whales died during migration, as all events occurred well south of known summer foraging areas. Given the small population size and the recognized male bias in western gray whales, loss of even a few animals to bycatch can cause significant negative effects on population growth potential and the risk of population-scale extinction. It was recognized in the early 2000s that Japanese legal protocols may have been contributing to bycatch risk by permitting fishers to sell meat or other products from bycaught whales. In 2008, new regulations were implemented that prohibit sale of products from bycaught whales and encourage fishers to release entangled whales alive when feasible. Sufficient time has not yet passed to determine the effectiveness of the new protocols.

Efforts are underway to determine migratory corridors and calving grounds for western gray whales, a reflection of intensive interest by the conservation community to identify the unknown portions of western gray whale distribution for purposes of eventual additional protection for the whales, in habitats critical to life history and survival. Satellite telemetry tags were attached to whales beginning in 2010, with continued effort in 2011. A surprising early development was the movement of an adult male from the Sakhalin Island region to the coastline of North America in autumn 2010, where it apparently joined the typical southbound autumn migration of eastern gray whales. Although the animal's transmitter failed in 2010 while it was southbound off the coast of Oregon, photoidentification surveys identified the same whale back at Sakhalin in summer 2011. Individuals in the western gray whale population are known to be genetically distinguishable from eastern gray whales, suggesting that exchange of breeding individuals between populations is uncommon. However, recent analyses involving geographic records for photographically identified individual whales indicate that other cases of movement between North Pacific populations have occurred in recent years. Additional tagging data will place the observed movements into perspective as well as serving the original purpose of locating migratory pathways and wintering habitats.

The summer feeding area near Zaliv Pil'tun has been subject to intensive exploration and development of marine oil reserves for the past two decades. Offshore petroleum exploration involves frequent use of "seismic surveys" that generate intensive low-frequency sounds, and development of located petroleum resources involves increased shipping activity, placement of structures, modification of adjacent sediments and benthic communities, and the risk of unintended spills of drilling fluids, vessel and machinery fuels, and extracted crude oil. The area now supports two large offshore production platforms linked to onshore infrastructure with subsea pipelines, and intensive shipping activity in support of petroleum extraction and transport. The possible addition of a third offshore production platform near Zaliv Pil'tun was announced by the industry in 2011.

Recovery planning for the western North Pacific gray whale population will benefit from acquisition of significant

additional data. There is a clear need for determination of winter range, calving grounds, migratory corridors, and improved insight into rates of genetic exchange with eastern North Pacific gray whales. An understanding of causes for the bias in population sex ratio will inform more effective and pragmatic population modeling. An improved understanding of the affinity of summering animals, and particularly females with dependent calves, for the feeding grounds off Zaliv Pil'tun will also support more effective conservation planning, as will ongoing critical assessments of activities associated with development of petroleum resources in the coastal zone of northeastern Sakhalin Island. Risks of extinction will be reduced significantly if observed rates of bycatch in fisheries along apparent migratory corridors can be eliminated.

Gulf of Alaska Beluga Whale: *Delphinapterus leucas* (Pallas, 1776)

The Gulf of Alaska population of beluga whales is normally concentrated in upper (northern) Cook Inlet on the southern mainland coast of Alaska. Individuals from this population have been seen on occasion in coastal waters of the Kodiak Archipelago, in Prince William Sound and Yakutat Bay, and along the outer coastal waters of the central Gulf of Alaska. Historically, belugas have been widely distributed within Cook Inlet, a turbid estuary subject to extreme tidal mixing and substantial freshwater input from several large river systems. The whales concentrate seasonally near and in the river mouths to forage on migrating salmon.

Belugas in Cook Inlet were hunted in previous decades by commercial whalers, although commercial harvest no longer occurs. Passage and implementation of MMPA in 1972 assured the rights of native peoples in Alaska to pursue the traditional practice of hunting beluga whales, including those in Cook Inlet. Hunting of belugas in Cook Inlet by natives increased in the 1980s and 1990s compared with earlier decades. During the 1990s, it was recognized that the geographic range of beluga whales, based on opportunistic observations from research vessels, was much smaller than it had been in the 1970s. No sightings of belugas in other locations of the Gulf of Alaska have been made in the recent years. Surveys in the 1990s confirmed that the population was declining. Recent survey data suggest a population size of approximately 340 individuals with no apparent trend in numbers over time. Based on known whale kills by native hunters and evaluation of survey data, it was determined that native harvest of belugas may have been excessive, possibly placing the Cook Inlet beluga population at risk of extinction. The population was listed as "endangered" in 2008 as per ESA, and is designated "critically endangered" as per RLTS. Native tribal organizations and US federal agencies are now planning for recovery actions and a more carefully regulated harvest under a comanagement framework that includes threshold population numbers, below which harvests will be prohibited.

The Cook Inlet beluga population is the first known modern case in which excessive harvest by indigenous North American peoples has placed a population of marine mammals in jeopardy. Other populations of belugas are exploited regularly by natives in Alaska, but none are in peril. The tenuous status of Cook Inlet belugas, compared with other Alaskan populations, probably results from three factors. First, the Cook Inlet

population probably has always been the smallest of the Alaskan beluga populations. Second, Cook Inlet belugas were subject to commercial whaling in previous decades. Third, the cultural characteristics of native harvest of belugas in Cook Inlet differ from all other locations in Alaska where native whaling occurs. In all cases except Cook Inlet, native whaling is done from single coastal villages, using practices consistent with lengthy tradition, subject to stringent oversight by village elders, and based on the subsistence needs of the village. In contrast, most native whalers working in Cook Inlet have moved from their home villages to the relatively large and secular city of Anchorage. Thus it appears that cultural norms and limits on whaling activity characteristic of native Alaskan villages have been lost in the case of Cook Inlet. A cautious and conservative comanagement approach to future harvests will best serve the sustainability of the Cook Inlet beluga population. Otherwise extinction is likely within the century.

Vaquita: Phocoena sinus Norris and McFarland, 1958

The vaquita is a small porpoise limited to the northern part of Golfo de California, Mexico. The vaquita has the smallest natural geographic range of any marine cetacean, and the single population probably has never contained a large number of individuals. Numbers are estimated at 500–600 individuals (Table 3). The population biology of the vaquita is poorly known. Even the most rigorous surveys of the vaquita population have low precision. Thus, trends in the population are difficult to discern with confidence. Available data suggest that the population may be declining at rates up to 15% per year. The vaquita is listed as “endangered” as per ESA and “critically endangered” as per RLTS.

In recent decades the primary concerns for vaquita conservation have been high rates of incidental take in gillnet and shrimp trawl fisheries, effects of contaminants, effects of reduced genetic diversity, and effects of diversion of the Colorado River away from the northern Golfo de California. Losses due to incidental take are currently viewed as the primary conservation problem. Concentrations of organochlorines, including PCBs and DDT congeners, are known to be low in vaquita tissues, low in other consumer species within the vaquita range, and low in the vaquita habitat. The levels of reduced genetic variability in vaquitas do not necessarily result in genetically based reduction of reproductive rates, particularly in the context of populations such as vaquitas that probably have always been small. Biological productivity in the upper Golfo de California is high compared with other coastal marine ecosystems despite diversion of the Colorado River.

Continued incidental take of vaquitas will likely cause extinction of the species during the twenty-first century, given even the most conservative estimates of the current rate of take. Elimination of the risk of anthropogenic extinction requires significant reduction in the level of fishing effort, or changes in gear design or deployment strategy to reduce take rates, in fisheries responsible for incidental take.

Mediterranean Monk Seal: Monachus monachus (Hermann, 1779)

The Mediterranean monk seal was found originally in the western Black Sea, throughout the Mediterranean Sea, and along the coast of northwestern Africa from the Strait of

Gibraltar to approximately 34° N latitude. At present, total numbers are estimated at approximately 600 seals, occurring primarily in two populations. One occurs in the eastern Atlantic on the Island of Madeira and along the coasts of Western Sahara and Mauritania in northwestern Africa. The second population occurs in the eastern Mediterranean, primarily off coastal Turkey and Greece. The largest concentration of seals currently known dwells in the coastal waters of Greece. Mediterranean monk seals are listed as “endangered” as per ESA and “critically endangered” as per RLTS.

Mediterranean monk seals probably have been subject to directed subsistence harvest for meat, oil, and hides for several millennia. The precarious status of modern populations seems to result from a number of factors associated with the large, multicultural human populations of southern and eastern Europe and northern Africa. For some years, monk seals have been perceived as direct competitors of fisheries, and have been harassed and killed in substantial numbers, often illegally, as a result. Harassment has included directed destruction of caves and other shoreline locations favored by seals for breeding and resting. Monk seals probably also have been affected by loss of prey due to overfishing and to various forms of contamination of habitats and food webs. In 1997 a mass mortality event was observed at a previously significant seal concentration at Cabo Blanco, near the border of Western Sahara and Mauritania, from an unknown cause. Although comprehensive demographic and population survey data are lacking, the consensus view is that the total number of Mediterranean monk seals is probably declining over time.

In addition to the small size of the two known populations, two factors add great difficulty to the prospects for implementation of a successful recovery strategy for Mediterranean monk seals. First, the habitat of the monk seal is bounded by a large number of culturally disparate political jurisdictions. Historically, political and cultural diversity in the region has interfered with cooperation among jurisdictions. Thus the attainment of consistent broadly supported conservation priorities for monk seals may be an unrealistic political objective. Second, ongoing damage to the monk seal populations apparently results from a number of factors acting in concert rather than one clearly pre-eminent problem. Thus, agreement on conservation priorities and actions may be difficult even within jurisdictions.

Mediterranean monk seals appear to be destined for extinction, possibly within the twenty-first century, unless marine conservation authorities in countries bordering seal habitat can agree in two areas. First, risk factors for the seals must be evaluated dispassionately and placed in order of significance. Second, involved authorities must agree on a plan for recovery of seal populations based on the assessment of risk factors and convince the human populations of their respective jurisdictions that seal conservation is a worthwhile objective.

Species, Subspecies, and Populations of Significant Concern with Regard to Extinction

Synopsis

Here we consider taxa or populations that are of significant concern with regard to extinction (Table 4). In contrast to the

Table 4 Species, subspecies, and populations of significant concern with regard to extinction

<i>Taxon</i>	<i>Population</i>	<i>Estimated population size^a</i>	<i>Current and historical risk factors</i>
Southern right whale: <i>B. glacialis</i> Müller, 1776 ^b	All	7000	CH, ITF, VC
Antarctic blue whale: <i>B. m. intermedia</i> Burmeister, 1871	Southern Ocean	Unknown	CH
Fin whale: <i>Balaenoptera physalus</i> (Linnaeus, 1758)	Northern hemisphere	40,000	CH
Fin whale: <i>B. physalus</i> (Linnaeus, 1758)	Southern hemisphere	20,000	CH
Sei whale: <i>Balaenoptera borealis</i> Lesson, 1828	All	65,000	CH
Humpback whale: <i>M. novaeangliae</i> (Borowski, 1781)	Oceania (Eastern Australia, Tonga, New Caledonia, Cook Islands, French Polynesia)	11,000	CH, ISW, SH
Hector's dolphin: <i>Cephalorhynchus hectori</i> (van Bénédén, 1881)	All	7500	CP, DIS, ITF, LRN, VC, VS
Atlantic humpback dolphin: <i>Sousa teuszi</i> (Kükenthal, 1892)	All	A few thousand	CP, HLP, ITF, LRN, SH, VC
Black Sea bottlenose dolphin: <i>Tursiops truncatus</i> (Montagu, 1821)	All	A few thousand	CP, CFP, CH, DIS, ITF, LCH, LRN
Irrawaddy dolphin: <i>Orcaella brevirostris</i> Owen in Gray, 1866	All	Unknown	CP, DD, ITF, LCR, LRN, TAM
Yangtze River finless porpoise: <i>Neophocoena phocoenoides asiaorientalis</i> (Pilleri and Gühr, 1972)	All	Unknown	CP, CFP, ITF, HLP, LRN
Baltic Sea ringed seal: <i>P. hispida botnica</i> (Gmelin, 1788)	All	Unknown	CP, DIS, ITF, LRN, MO, OW, SH, VN
Caspian seal: <i>Pusa caspica</i> (Gmelin, 1788)	All	111,000	CFP, CH, CP, DIS, ITF, OW, PO, PR
Lake Ladoga ringed seal: <i>P. hispida ladogensis</i> (Nordquist, 1899)	All	Unknown	CP, LRN, OW, SH, VN
Western North Pacific harbor seal: <i>P. vitulina stejnegeri</i> Allen, 1902	All	6500–7500	ICF, ITF
Steller's sea lion: <i>E. jubatus</i> (Schreber, 1776)	Western North Pacific	58,000–66,000	CFP, FLI, IHC, ITF, PR
Australian sea lion: <i>Neophoca cinerea</i> (Péron, 1816)	All	13,800	CH, DT, ITF, SH
Hooker's sea lion: <i>Phocartos hookeri</i> (Gray, 1844)	All	12,000	CFP, CH, DIS, DT, ITF, LRN, SH
Guadalupe fur seal: <i>Arctocephalus townsendi</i> Merriam, 1897	All	7000	CH, LRN
Juan Fernandez fur seal: <i>Arctocephalus philippii</i> (Peters, 1866)	All	12,000	CH, ITF, LRN, MDI, PO
Atlantic walrus: <i>O. rosmarus rosmarus</i> (Linnaeus, 1758)	All	20,000	CH, CP, DIS, OW, PO, SH
Laptev Sea walrus: <i>O. rosmarus laptevi</i> Chapskii, 1940	All	4000–5000	CH, CP, OW
Amazonian manatee: <i>Trichechus inunguis</i> (Natterer, 1883)	All	Unknown	CH, CP, DD, ITF, LRN, SH, TAM
West African manatee: <i>Trichechus senegalensis</i> Link, 1795	All	Less than 10,000	CH, PO, SH, TAM
West Indian manatee: <i>T. manatus</i> Linnaeus, 1758	All	6400–9400	CH, CP, DD, ITF, MDI, SH, TAM, VC, VN
California sea otter: <i>E. I. nereis</i> (Merriam, 1904)	All	2800	CP, CH, DIS, ITF, MO, PR
Northern sea otter: <i>E. I. kenyoni</i> Wilson, 1991	All	78,000	CP, CH, ITF, MO, PR

^aIndicated estimates of population size reflect a wide range of quantitative rigor. Primary sources for estimates shown are online resources associated with NMFS, FWS, and RLTS. The responsibility for errors rests exclusively with the authors of this article.

^bSome taxonomists consider the southern right whale a separate species, *B. australis* (Desmoulins, 1822). Here, we follow the convention of Rice (1998), regarding the northern and southern right whales as one species.

Codes for risk factors are as shown in Table 3.

section Species, Subspecies, and Populations in Imminent Peril of Extinction, we do not regard entries in this group to be in imminent peril of extinction during the twenty-first century. In most cases, population sizes are large enough and conservation issues tractable enough that less dire predictions seem more reasonable. Proactive management will be required to prevent taxa and populations in this group from reaching a more precarious status. We list 27 taxa or populations (Table 4), providing more detailed summaries for five arbitrarily selected examples.

Blue Whale: *Balaenoptera musculus* Linnaeus, 1758

Blue whales occur in coastal and pelagic marine habitats worldwide. Currently three subspecies are known. The pygmy blue whale (*B. musculus breviceuda* (Ichihara, 1966)) occurs in southern cool temperate and subpolar latitudes. The Antarctic blue whale (*B. musculus intermedia* (Burmeister, 1871)) summers in the Antarctic Ocean, and the northern blue whale (*B. musculus musculus* (Linnaeus, 1758)) is found in the North Pacific and North Atlantic. Eastern and western populations are known in the North Atlantic, and at least five populations have been described in the North Pacific. The population structure in the southern hemisphere is unclear. All blue whale populations and subspecies are listed as “endangered” pursuant to ESA and “endangered” as per RLTS, throughout their respective geographic ranges. Available data suggest that blue whales migrate seasonally, utilizing higher latitude habitats in summer for feeding primarily on euphausiid crustaceans (“krill”), and lower-latitude habitats during winter for courtship, breeding, and parturition. The spatial scope of blue whale migrations appears less than those of iconic migrating species such as gray and humpback whales. In addition, there is evidence that individual blue whales may transit the full length of their migratory corridors asynchronously several times annually in response to spatial and temporal variations in prey availability.

Blue whales are an obvious target of choice for commercial hunting because of their great body size. However, blue whales are swift swimmers and are negatively buoyant *post mortem*. Before exploitation, blue whales were most abundant in the Antarctic Ocean and other marine habitats distant from human population centers. Thus, they were beyond the technological capabilities of commercial whalers before the twentieth century. Blue whales became priority targets of whalers only after development of the steam engine, factory ships, explosive harpoons, and air compressors to inflate carcasses after killing. Thus the harvest and depletion of blue whales occurred primarily during the twentieth century. At least 360,000 blue whales were killed in the Antarctic region before commercial whaling declined in the 1960s, and other populations were exploited as well. Illegal harvests by Soviet whalers occurred after a moratorium was imposed on blue whale catches by the International Whaling Commission (IWC) in 1965. At least 8000 additional pygmy blue whales were taken.

The consensus view at present is that blue whale populations are now but a fraction of pre-exploitation size. Recent data indicate that the combined North Pacific populations number approximately 3300 individuals. The combined North Atlantic populations have been estimated at 100–600

individuals. The estimated numbers of blue whales in southern hemisphere habitats range from 400 to 1400 (all subspecies combined). There are published arguments that blue whale populations off southern Japan, in the eastern Gulf of Alaska, and off northern Norway are locally extinct or quite small. In contrast, blue whale numbers seem to have increased rapidly off northern California since the 1970s, suggesting that redistribution may be a contributing factor to regional trends. Because of small population sizes and large CV associated with surveys, it is often not possible to identify trends in blue whale populations. The survey effort required to collect data sufficiently powerful for trend detection is prohibitively costly. Thus, the status of the world’s blue whale populations is generally poorly known, and prospects for confident understanding of status of populations in the foreseeable future are limited.

The current status of blue whale populations seems to be largely the result of excessive past commercial harvests, including illegal Soviet whaling. There is evidence that ship-strikes and entanglement in fishing gear may cause some mortality of blue whales in some coastal habitats, but current anthropogenic mortalities are probably minimal. Recovery of small blue whale populations may require indefinite suspension of all forms of harvest, and prompt detection and elimination of emerging sources of anthropogenic mortality.

Western North Pacific Steller’s Sea Lion: *Eumetopius jubatus* (Schreber, 1776)

Steller’s sea lions occur in coastal waters of the North Pacific Rim from southern California to northern Japan, and in the Bering Sea. In body mass they are the largest of the world’s otariids, with males averaging 1000 kg. Genetic data have been used as the basis for dividing the species into two populations, western and eastern, with the boundary at Cape Suckling (144° W longitude), Alaska. Both populations are designated “endangered” as per RLTS. The eastern population is dispersed along the west coast of North America, numbers approximately 52,000 individuals, is increasing slowly overall, and is listed as “threatened” as per ESA. The western population numbered approximately 150,000 animals in the 1950s, but has since declined precipitously, with current total numbers, including US and Russian habitats, estimated at between 58,000 and 66,000 individuals. The rate of decline has varied over time, with the highest rates (approximately 15% per year) from 1985 until 1990. The western population is listed as “endangered” as per ESA. The population is currently thought to be stable overall, but with significant variation in trends among locations within the range of the population. The same local-scale variance in trend is known for the eastern population.

The cause or causes of long-term decline in the western population of Steller’s sea lions are not understood. Possible risk factors include incidental take in fishing gear, competition with fisheries for prey in common, hunting by indigenous peoples, illegal hunting or harassment, inadvertent rookery disturbance, consumption by killer whales, disease or parasitism, contaminants, and changes in the structure and productivity in the marine ecosystems of which Steller’s sea lions are part. Based on extensive research since the decline was first recognized, the consensus view at present is that ecosystem

change and competition with fisheries are the factors most likely driving the decline. Resolution of the question of cause has become the focus of intensive political interest because of the potential economic consequences of resulting recovery actions by management authorities. The groundfish fisheries of the Gulf of Alaska and the Bering Sea are the most valuable and highly capitalized of the fisheries in the coastal waters of the US. Steller's sea lions feed extensively on groundfish species, such as walleye pollock, targeted by fisheries. Determination that competition with fisheries is contributing to the decline could result in forced reduction of fishing effort, with great economic loss and political discord.

Several lines of evidence favor the argument that ecosystem change has contributed to the decline in sea lion numbers. Prey species composition has changed and dietary diversity has declined, and there have been measurable shifts in the spatial distributions of preferred prey over the past three decades. Numbers of other piscivores in the habitat, including seabirds and harbor seals, have declined over a similar time scale in many parts of the sea lion range. However, fishing activity may be intensive near important breeding locations, and it has not been possible to eliminate competition with fisheries as a potential cause of the decline. Recent rulings in US federal courts have restricted fishing activity in some locations and seasons for the purpose of reducing the rate of decline, intensifying the associated political debate. Because natural oceanographic changes can neither be predicted nor controlled, management authorities may have no choice but to focus on understanding and minimizing anthropogenic risk factors, despite the political consequences, in order to reduce the probability of eventual extinction.

West Indian Manatee: *Trichechus manatus* Linnaeus, 1758

The West Indian manatee occurs in coastal habitats and the lower reaches of rivers in the southeastern US, the Islands of the Caribbean Sea, and the mainland shores of the Gulf of Mexico, the Caribbean coast of Central America, and north-eastern South America. Two subspecies are recognized. The Florida manatee (*T. manatus latirostris* (Harlan, 1824)) is found in US coastal waters, especially in Florida. The Antillean manatee (*T. manatus manatus* (Linnaeus, 1758)) occupies the remainder of the range of the species. The current population in Florida is the largest of the species, numbering approximately 3800 individuals, with annual rates of increase in the range of 2–4%. Population structure, numbers, and trends in other locations are not well known, with estimates of total numbers of Antillean manatees ranging from 2600 to 5600 individuals. The species is listed as “endangered” as per ESA and “vulnerable” as per RLTS throughout its geographic range.

Manatees have been hunted by indigenous peoples for meat and other products for centuries. Commercial hunting probably contributed to a reduction of population sizes, but there are few data available to assess the rates or the significance of commercial harvest. Manatees have been protected from all forms of directed harvest in Florida since the 1960s, but subsistence harvest continues in other populations, for meat and oil and for ceremonial purposes. During the twentieth century a number of risk factors for manatees emerged, all in association with an expanding human population in

immediate proximity to manatee habitat. The primary problems are increased levels of contaminants and a variety of modifications and ongoing disturbances of habitat. The latter include watercourse diversions and impoundments in aquatic manatee habitat, and disturbance and collision risk associated with recreational boating.

Long-term studies of stranded carcasses indicate three major sources of mortality in Florida manatees. Perinatal mortalities involve newborn animals with the proximate cause of death uncertain, but possibly linked to contaminants. Significant mortality rates are also associated with entrapment in dam floodgates, entanglements in fishing gear, and collisions with recreational powerboats. Manatees clearly prefer areas without significant powerboat traffic, and the ongoing expansion of human populations and associated demand for recreational opportunities inevitably lead to continuing reduction in the size of available manatee habitat.

Manatees are particularly sensitive to water temperature compared with other marine mammals and typically congregate in warm water refugia during winter, especially when ambient sea surface temperatures drop below approximately 18 °C. Refugia include natural warm aquatic springs, and lagoons associated with thermal effluent from electrical generating plants. Natural refugia for manatees are few in number and generally small in size, such that their value to manatee conservation may be highly sensitive to threats from encroaching effects of human development and activity. Use of power plant lagoons may be risky if plant operations dictate precipitous shutdown, resulting in cutoff of thermal effluent and rapid chilling of lagoons. Manatees in Florida have experienced several significant mass mortalities in the recent decades, possibly resulting from an interaction of contaminants, compromised immune systems, disease, and natural toxins associated with harmful phytoplankton blooms.

Habitat loss and disturbance are the primary conservation problems for all populations of West Indian manatees, and subsistence or illegal harvest remain significant risk factors for populations outside of Florida. Over the long term, avoidance of extinction may require cessation of all forms of human harvest and an effective, broadly supported strategy for balancing the habitat needs of manatees with the consequences of human population growth, especially in Florida.

California Sea Otter: *E. lutris nereis* (Merriam, 1904)

Sea otters originally ranged throughout the coastal waters of California, including San Francisco Bay and the southern California islands, and probably numbered 16,000–20,000 individuals before the onset of commercial-scale harvests for pelts in the eighteenth century. The population originally extended southward into mainland Baja California and Isla Guadalupe, Mexico, and was contiguous with other otter populations ranging through the North Pacific Rim to northern Japan. Sea otters in California comprise one of three subspecies currently recognized.

Sea otters probably have been hunted by the indigenous peoples of the North Pacific Rim for several millennia, for meat and pelts and for ceremonial purposes. Observations of the Bering Expedition of 1741–1742 and other voyages of exploration in the North Pacific found sea otters to be abundant throughout their range, and commercial harvest of sea

otters for pelts began soon after. In California the harvest was pursued by hunters from Russia, often utilizing enslaved Aleut hunters, and from Spain, Mexico, and the US. All commercial hunts for sea otters were terminated with approval of the Treaty for the Preservation and Protection of Fur Seals (37 Stat. 1542, T.S. No. 542) by Japan, Russia, Great Britain (on behalf of Canada), and the US. The Treaty was proclaimed in 1911 and ratified in 1912. Article V of the Treaty afforded protection to sea otters from further hunting. Protection of sea otters from hunting in US waters was extended by Presidential Proclamation in 1913 by US President Wilson, and by Executive Order in 1929 by President Coolidge. The State of California enacted regulations to prohibit hunting of sea otters in 1913. However, in California and Mexico the sea otter populations had been depleted commercially by the 1860s. By 1900 only two small populations survived. One was along the Big Sur coast south of the Monterey Peninsula, numbering approximately 50–100 animals. The second, of unknown size off the Islas San Benitos, Mexico, was extinct by the 1920s. The Big Sur population grew at a rate of approximately 5% per year through much of the twentieth century and now numbers approximately 2800 animals, ranging from near Half Moon Bay in San Mateo County southward to the vicinity of Cojo Anchorage in Santa Barbara County. The observed rate of growth in California is currently approximately 3% per year, much lower than rates commonly observed in more northerly populations with protection from harvest and available adjacent vacant habitat. In the late 1980s a new colony was established by translocation at San Nicolas Island (SNI) off southern California. The SNI colony now numbers approximately 50 animals, shows consistent local pup production, and is growing slowly in number, fostering increasing optimism for long-term persistence, *Reeves et al.* (2002) to the contrary notwithstanding. The California sea otter population is listed as “threatened” as per ESA and is designated “endangered” by RLTS.

Several risk factors are known for sea otters in California. Near-shore set-net fisheries were responsible for significant rates of incidental take in the late twentieth century. Changes in fishery regulations have reduced but not eliminated incidental take. Sea otters are known to compete with near-shore marine shellfish fisheries in California, particularly for abalones, sea urchins, clams, and crabs. Concern about interactions of sea otters and shellfisheries is significant, often leading to controversy among scientists, managers, and stakeholders. There is long-standing concern about illegal killing of sea otters to protect shellfisheries, but little solid evidence of a significant problem. Since the 1980s shark attack has been recognized as a significant source of sea otter mortality, particularly in the northern portion of the current range, where great white sharks are relatively common. In the recent decades new concerns have emerged regarding a range of diseases and parasitic infestations that may be highly significant sources of sea otter mortality. In some cases, diseases may have been introduced to sea otters by way of anthropogenic infrastructure such as domestic sewage outfalls, whereas others may have dispersed naturally from terrestrial mammal populations. Increased occurrence of exotic intestinal parasites from unknown sources, particularly a species of acanthocephalan not previously known in sea otters, has been associated with

significant rates of fatal peritonitis in the population. The California sea otter population is also regarded to be at high risk of potential damage from oil spills, associated with significant tankship traffic and marine petroleum development, both implemented and proposed, in coastal marine habitats either occupied or suitable for occupation by sea otters. Oiling mats the pelage and eliminates the thermoregulatory function of sea otters, leading rapidly to chilling and death. Oiling is also known to cause other pathologies. The *Exxon Valdez* oil spill of 1989 in Prince William Sound and adjacent waters, Alaska, killed hundreds of sea otters and provided extensive opportunities for detailed insights into pathologies resulting from oiling of animals. The event validated concerns about potential population-scale damage to sea otter populations wherever they overlap in space with marine petroleum extraction, transportation, or processing activities.

A clear consensus on the cause or causes of relatively low growth rates of the California sea otter population has not emerged. Primary risk factors are thought to be ongoing incidental taking in fishing nets, effects of contaminants, mortalities from diseases and exotic parasites, and shark attacks. There is a perception that sea otters in California are more susceptible to disease impacts as compared with other sea otter populations. The long-term survival of the sea otter population in California will likely require ongoing research to more effectively characterize current risk factors, and the development of strategies to minimize associated mortalities. The large and growing human population in California is a major underlying cause of the jeopardy status of sea otters, and broad popular support, including economic compromise by shellfishery and marine oil interests, likely will be required if recovery is to be successful.

Northern Sea Otter: *E. lutris kenyoni* Wilson, 1991

The original geographic range of the northern sea otter extended from Attu Island, at the western extreme of the Aleutian Archipelago, Alaska, eastward and southward along the coasts of Alaska, British Columbia, Washington, and Oregon. Sea otters currently dwelling in waters off Washington, British Columbia, and southeastern Alaska are descended from animals reintroduced in the 1960s and 1970s. Source populations in all cases were northern sea otters moved from either Amchitka Island or Prince William Sound. As noted in Section “California Sea Otter: *E. lutris nereis* (Merriam, 1904)”, large-scale commercial hunting of sea otters for pelts began in 1741. It is estimated that between 500,000 and 900,000 northern sea otter pelts were taken during the commercial harvest period. When legal hunting ended in 1911, the number of surviving northern sea otters was probably between 1000 and 2000 individuals, scattered among seven isolated remnant populations from the Queen Charlotte Islands, Canada, to the Rat Island group of the Aleutian Archipelago. The Queen Charlotte population was extinct by 1920. The northern sea otter has been subject to ongoing subsistence harvest by native peoples for meat and pelts, probably for many centuries.

Populations from Prince William Sound westward largely recovered from effects of the fur harvest period without assistance, other than prohibition of harvest, during the twentieth century. Observed annual population growth rates were as high as 10–15% in some cases. The translocation projects

done in the 1960s and 1970s restored northern sea otters to habitats vacated by excessive fur harvests in southeastern Alaska, British Columbia, and Washington.

Legal subsistence harvest of northern sea otters by native villages in Alaska has averaged approximately 500 animals per year since the mid 1980s, pursuant to MMPA. The harvest is concentrated primarily in Prince William Sound and southeastern Alaska. The *Exxon Valdez* oil spill of 1989 killed between 500 and 2500 sea otters in Prince William Sound and nearby coastal areas. Despite the intensive public interest and media coverage that fed into apocalyptic scenarios, it appears that sea otter numbers in the Sound did not experience long-term reduction, with the possible exception of a few local areas most heavily affected by the oil spill. Some effects on sea otter prey populations and habitats may persist even to the present, but sea otter numbers are large and growing in most areas affected by the spill. The most recent surveys of sea otters in Prince William Sound, done in 2003, produced a population estimate of approximately 12,000 animals.

Northern sea otter populations number approximately 78,000 individuals, summed across all habitats in Alaska, British Columbia, and Washington. For management purposes, northern sea otter populations in Alaskan waters have been divided into three geographic stocks: Southeast (east of Cape Yakataga through southeastern Alaska to Dixon Entrance), Southcentral (Cape Yakataga west–Cook Inlet including Prince William Sound and Kachemak Bay), and Southwest (west of Cook Inlet including the Alaska Peninsula, Kodiak Archipelago, Bristol Bay, and Aleutian Archipelago). The Southwest Stock is listed as “threatened” as per ESA. The Southcentral and Southeast Stocks and the Washington population are not listed as per ESA. All northern sea otter stocks and populations are designated “endangered” as per RLTS. The British Columbia population is classified as “of special concern” by the Committee on the Status of Endangered Wildlife in Canada.

The most recent northern sea otter population estimate for the US Southwest Stock is approximately 47,700 animals and suggests an increasing trend over the previous several years. However, the recent data do not capture extraordinary fluctuations in the region in the recent decades. It is estimated that the Stock declined in numbers by over 50% from the mid 1980s to the beginning of the twenty-first century. The decline in numbers continued into the early 2000s, with numbers decreasing by 63% in 2 years in the central Aleutian Islands and 48% over the same period in the eastern Aleutians. The declines apparently did not occur in the Kodiak Archipelago or along portions of the Alaska Peninsula, and growth in the latter areas apparently has resulted in an overall recent increase in numbers in the stock despite the population-scale collapses in the Aleutian Islands.

The most broadly accepted explanation for the extreme declines is an abrupt increase in predation by killer whales of the mammal-eating (“transient”) ecotype on sea otters beginning in the late 1980s and the early 1990s. The principal lines of evidence for areas showing the most precipitous declines include absence of beach-cast sea otter carcasses, despite high search effort and the knowledge that prior periods of food stress produced substantial numbers of beach-cast carcasses; excellent body condition and lack of disease or other

pathologies in surviving sea otters; high abundance of preferred prey; higher observed survival in sea otters occupying habitats with physiographic barriers to killer whale access as compared with areas with whale access; the presence of foraging killer whales; and occasional observations of attacks by killer whales on sea otters. The killer whale predation hypothesis has also engendered skepticism, primarily because of the small number of direct observations of attacks by killer whales on sea otters and because of the minimal value of an ingested sea otter to the metabolic needs of a killer whale.

The credibility of the killer whale hypothesis has been damaged by a second published hypothesis to explain the inferred shift in killer whale diet from larger marine mammals to sea otters. The “serial depletion” hypothesis argues that commercial whaling in past decades in the North Pacific region reduced availabilities of preferred prey of mammal-eating killer whales. The postulated result was a series of prey population depletions, with killer whales shifting sequentially to smaller and less rewarding prey items following over-exploitation of larger prey. The hypothesis suggests that sea otters became vital prey when populations of larger marine mammals, particularly pinnipeds, became too rare to sustain the whales metabolically. Publication of the hypothesis drew a series of published rebuttals and remains controversial. However, regardless of the underlying cause, we find it difficult to argue with evidence that the collapse of some northern sea otter populations has been caused primarily by killer whale predation. We view the evidence to be compelling and inconsistent with any plausible alternative explanation.

The northern sea otter clearly recovered from the excessive harvests of the seventeenth, eighteenth, and nineteenth centuries. Current sources of concern include negative interactions with fishing gear and vessels, proper management of legal harvests by native hunters, illegal harvests, and possible damage from chemical contamination, including oil spills. The primary concern, however, is the threat of extreme consumption rates by killer whales. There is no feasible and politically tractable management intervention that can reduce killer whale predation on free-ranging sea otter populations. However, predators rarely exploit prey to the point of extinction and it seems more likely that the whales will switch to different prey when faced with a diminished supply of sea otters. Contrary to the proponents of the serial depletion hypothesis, we suggest that the whales have a number of alternative prey, all larger and more valuable metabolically than sea otters, to which they will likely switch long before whale predation by itself places the northern sea otter in peril of extinction. Beyond the issue of killer whale predation, northern sea otters will likely remain out of jeopardy, as long as legal harvests are conservatively regulated, and all feasible efforts are made to reduce or eliminate incidental takes by fishing activity, illegal harvests, and the effects of contaminants and oil spills.

As noted above and in Section “California Sea Otter: *Enhydra lutris nereis* (Merriam, 1904)”, translocations have made significant contributions to the restoration of sea otter populations in several regions. Here we explore the role and significance of translocation projects in greater detail. Sea otters are unique among the marine mammals in the tractability of population-scale translocation projects as a conservation tool.

Compared with other marine mammals, sea otters are small in body mass, can be captured with relative ease and with some control over age and gender of targeted animals, and tolerate temporary captivity and transportation reasonably well. The utility of population-scale relocation efforts as a conservation tool for sea otters has fallen out of favor among management authorities, in part because the implementation of such projects is costly, politically challenging, and because completion of requisite associated logistical, administrative, and legal tasks may require up to a decade in advance of the movement of animals. In addition, individual animals involved in relocation may be placed at risk. Six major sea otter translocation projects were initiated between 1965 and 1987 in the US and Canada. Each had the intent of restoring populations to regions from which sea otters had been hunted to extinction during the eighteenth, nineteenth, and early twentieth centuries. With one exception, animals to be relocated were captured from northern sea otter populations at Amchitka Island and Prince William Sound, Alaska. The recipient regions for translocation were vacant sea otter habitats in southeastern Alaska (initiated in 1965), the Pribilof Islands (1968), British Columbia (1969), Washington (1969), Oregon (1970), and SNI (1987). The source population for the SNI project was the California sea otter population along the mainland California coast. In each case, initial postrelease losses of sea otters, either by documented death or by dispersal to unknown locations, were typically in the range of 70–90%, causing justifiable alarm. In the Pribilof Island and Oregon cases, otter numbers dwindled to near zero and the projects were deemed unsuccessful, although single animals can be observed occasionally in both locations to the present. Three of the four other efforts (southeastern Alaska, British Columbia, and Washington) ultimately emerged as highly successful, producing populations with a summed total currently estimated at approximately 15,000 individuals, with numbers either stable or growing in all cases. The re-established population in southeastern Alaska now appears to be stable at 9000–10,000 individuals and supports sustained subsistence harvests by native hunters of up to several hundred animals per year.

The fourth and most recent project (SNI) also included high initial postrelease loss rates. Many of the relocated animals likely died following misdirected dispersal from SNI, but the project revealed for the first time the strong large-scale site fidelity of sea otters, with nearly one-third of relocated animals (all of which were tagged with visual color-coded markers on the flippers) returning across minimum distances of up to 400 km to original capture sites on the mainland California coast. Thus, instinctive homing, in many cases spatially misdirected, may have driven early losses of released animals observed in all translocation projects. Although the ultimate success level of the SNI project remains uncertain 25 years after implementation, the recent data are increasingly encouraging as noted. With the exception of prohibition of unregulated commercial harvest, implementation of translocation projects has produced conservation dividends that far exceed any other management action taken on behalf of sea otters since development of the International Fur Seal Treaty in 1911. Translocation projects have substantial conservation value if the requisite and daunting prior investment in time, effort, and funds can be managed.

Species, Subspecies, and Populations Once Thought to be Near Extinction, Now Showing Evidence of Recovery

Synopsis

Here we summarize data for 10 species, subspecies, or populations of marine mammals that have been near extinction in the recent past, but are now either recovered or apparently enroute to recovery (Table 5). We regard the taxa or populations in this group as unlikely to become extinct in the foreseeable future as long as risk factors presently unknown do not appear. In this section we present case summaries for four taxa, selected arbitrarily, to illustrate patterns typical of the group.

Western Arctic Population of the Bowhead Whale: *Balaena mysticetus* Linnaeus, 1758

Bowhead whales occur in at least five populations in northern habitats characterized by frequent sea ice. Four of the five populations are small and at risk of extinction (Table 3). The western Arctic population is by far the largest, numbering approximately 10,500 individuals, with annual growth rates averaging 3.5%. The population occurs in the Bering, Chukchi, and Beaufort Seas, migrating northeasterly to the Beaufort Sea in spring, and returning to the Bering and Chukchi Seas in autumn each year. The population is listed as “endangered” as per ESA, and is designated as “lower concern – conservation dependent” by RLTS.

The population probably numbered between 10,000 and 23,000 individuals when first exploited by US whalers during the late 1840s. By the demise of the commercial harvest in 1919 approximately 20,000 whales had been taken, and the population was thought to number between 1000 and 3000 individuals.

Bowhead whales have been hunted for subsistence and ceremonial purposes by the indigenous peoples of Alaska, western Canada, and Russia for many centuries. Alaskan native villages continue to harvest whales from the western Arctic population based on a quota approved by IWC and managed jointly by representatives of native villages and US federal agencies. Management policies have been successful, allowing continued growth of the population despite annual hunts for whales by several villages. In the recent years the annual harvest from the western Arctic population by native villages in Russia, the US, and Canada has averaged 41 whales. For a number of years there has been concern about effects of marine petroleum exploration and development activities in the habitat of bowhead whales, especially in the Beaufort Sea. Offshore oil activity is known to influence movement patterns of whales during migration, but demographic effects have not been demonstrated. A recent increase in active and proposed marine oil development along the Arctic coast of Alaska has renewed concerns regarding conservation implications for bowhead whales.

The western Arctic bowhead whale population appears to be recovering while other bowhead whale populations are not. The likely primary reason is that other populations were pushed much closer to extinction by commercial whaling, possibly imposing depensatory effects and limiting the capacity for recovery. It appears that the western Arctic population will continue to grow, perhaps approaching carrying capacity

Table 5 Species, subspecies, or populations once thought to be near extinction, now showing evidence of increasing numbers

<i>Taxon</i>	<i>Population</i>	<i>Estimated population size^a</i>	<i>Current and historical risk factors</i>
Bowhead whale: <i>B. mysticetus</i> Linnaeus, 1758	Western Arctic (Bering, Chukchi, and Beaufort Seas)	10,500	CH, MO, SH
Humpback whale: <i>M. novaeangliae</i> (Borowski, 1781)	All except Oceania (IWC breeding stock "E") and Arabian Sea	50,000–60,000	CH, ITF, VC, VN
Gray whale: <i>E. robustus</i> (Lilljeborg, 1861)	Eastern North Pacific	20,000	CH, ITF, VC, VN
Eastern spinner dolphin <i>Stenella longirostris orientalis</i> (Perrin, 1990)	All	613,000	ITF
Northern elephant seal: <i>M. angustirostris</i> (Gill, 1866)	All	125,000	CH
California sea lion <i>Z. californianus</i> (Lesson, 1828)	All	250,000	CH, CP, FLI, IHC, ITF, MDI, SH
Galapagos fur seal: <i>Arctocephalus galapagoensis</i> Heller, 1904	All	30,000–40,000	CH, ITF, FLI
Subantarctic fur seal: <i>Arctocephalus tropicalis</i> (Gray, 1872)	All	270,000–360,000	CH
Antarctic fur seal: <i>Arctocephalus gazella</i> (Peters, 1875)	All	Approaching 4,000,000	CH
Russian sea otter: <i>E. lutris lutris</i> (Linnaeus, 1758)	All	20,000	CH, CP, MO, PO

^aIndicated estimates of population size reflect a wide range of quantitative rigor. Primary sources for estimates shown are online resources associated with NMFS, FWS, and RLTS. The responsibility for errors rests exclusively with the authors of this article.

Codes for risk factors are as shown in Table 3.

within the current century, as long as harvests by native villages are regulated conservatively, and as long as other significant risk factors do not emerge.

Humpback Whale: *Megaptera novaeangliae* (Borowski, 1781)

Humpback whales are distributed globally in marine habitats. At least seven populations are recognized in the southern hemisphere: three in the North Pacific, one in the North Atlantic, and an unusual nonmigratory population in the Arabian Sea. Humpback whales often occur near shore. Lengthy seasonal migrations between high-latitude summer feeding areas and low-latitude winter breeding areas are well documented for all populations except for the Arabian Sea whales.

Humpback whales were among the earliest targeted species of commercial whalers because of their abundance, large size, and coastal distribution. During twentieth-century commercial hunts in the southern ocean, several hundred thousand individuals were taken. Illegal harvest by whalers from the USSR was extensive and potentially damaging to populations following the decline of large-scale legal commercial whaling. Subsistence harvest by indigenous peoples was common in the previous centuries. Additional modern risk factors include shipstrikes, incidental take in fishing nets, and habitat disturbance by large recreational cruise ships. All humpback whales populations are listed as "endangered" as per ESA. RLTS designates populations in the Arabian Sea and Oceania (the latter including eastern Australia, Tonga, New Caledonia, the Cook Islands, and French Polynesia) as "endangered". Other populations are not listed as per RLTS.

Although trends in most populations have not been confidently documented, there is a broad perception that humpback whale numbers are increasing on a global scale. Recent

estimates are 11,500 individuals in the North Atlantic, and a combined total of 21,000 individuals in the North Pacific. Population growth rate estimates range from 3% to 7% per year. Data from the southern hemisphere and the Arabian Sea are not sufficient to develop confident population estimates or characterize trends.

The population wintering near Tonga, in the western South Pacific, experienced excessive subsistence harvests during the twentieth century. A moratorium was placed on the harvest of humpback whales by the Tongan government in 1978, when it was recognized that the number of whales breeding in Tongan waters was seriously depleted and that further subsistence harvest was not sustainable. As noted above, the Tongan breeding population of humpback whales is lumped with breeding whales at other locations as a single breeding stock by IWC. However, IWC recognizes the Tonga case as an identifiable substock, facilitating improved scrutiny. Humpback whales in the Arabian Sea are found from approximately the Gulf of Aden eastward to Sri Lanka. The population was reduced over the long term by commercial whaling, and more recently by illegal Soviet whaling and entanglement in fishing gear. It appears there may be a few hundred animals in the population.

The eastern and western North Pacific populations of humpback whales remain small enough to be of ongoing concern in a conservation context, and the relatively small Arabian Sea population may not be able to sustain current levels of incidental taking by local fisheries. We suggest that prospects for survival of humpback whales, as a species, are good as long as commercial and subsistence harvests remain suspended, incidental taking is reduced, and habitat disturbance by human activities continues to be restricted and carefully monitored.

Eastern North Pacific Gray Whale: *E. robustus* (Lilljeborg, 1861)

The eastern North Pacific population of gray whales ranges from the Bering, Chukchi, and Beaufort Seas of the Arctic region during summer to the shallow protected coastal lagoons of Baja California Sur, Mexico, during winter months. Eastern gray whales were hunted intensively by commercial whalers from the eighteenth through the early twentieth centuries. The population may have reached a minimum of approximately 4000 individuals in the late 1890s. The population numbered approximately 13,000 when regular quantitative surveys were begun in 1967. Based on standardized surveys done from 1967 through 2007, the current population is thought to be 20,000 individuals, with a mean annual growth rate of 3.3%. The time series includes a dramatic mortality event in 1999 and 2000 apparently linked to fluctuating prey availability. Patterns in population trend, observed adult mortality rates, and the number of whales in unusual locations during summer are all consistent with the perception that the population is approaching carrying capacity. In 1994 the eastern gray whale was the first marine mammal to be removed from the List of Endangered and Threatened Wildlife as defined by ESA. The eastern gray whale is not listed by RLTS.

Several risk factors are of current concern for eastern gray whales. Modest rates of incidental take in fishing nets are reported. Disturbances by boats supporting "whale watching" activities are of concern, both in migratory corridors along the heavily populated west coast of North America and especially in the breeding and calving lagoons in Mexico. As with all large cetaceans, mortalities from shipstrikes are a chronic risk factor for gray whales.

Eastern gray whales are subject to ongoing annual subsistence harvests by indigenous peoples in Russia, Alaska, and Washington State. The subsistence harvests are authorized by IWC quota and are managed by village elders and government agencies in Russia and the US. Subsistence hunts have taken approximately 100 whales per year for several decades, with most of the harvest occurring along the Russian coast of the Bering and Chukchi Seas during summer months. In 1998 the Makah tribe of northwestern Washington State was allocated a harvest quota of five whales, in exchange for a reduction of the quota by five whales for Russian and Alaskan hunts. The allocation of harvest quota to the Makah people was consistent with the Treaty of Neah Bay of 1855 (12 Stat. 939), between the Makah tribe and the US government. One whale was taken in 1999 by Makah hunters. The extraordinary public interest, political discord, and coverage by news media were vastly disproportionate to the demographic significance of the hunt. Owing to a range of US federal legal proceedings and court rulings, Makah tribal hunters have harvested no additional gray whales since 1999 pursuant to the IWC quota. One gray whale was killed illegally by five Makah tribal members in 2007.

In our view the eastern gray whale population is no longer at risk of extinction in the foreseeable future. The status of the population should remain stable and sustainable as long as subsistence harvests are conservative and carefully managed. Rigorous monitoring and appropriate management responses to increasing problems with incidental taking, disturbance by boats, and shipstrikes will increase the probability that the population will remain out of jeopardy.

Northern Elephant Seal: *Mirounga angustirostris* (Gill, 1866)

Northern elephant seals breed and molt on coastal islands and isolated mainland sites of Baja California, Mexico, and southern and central California, US. When not hauled out, seals forage in pelagic habitats of the temperate and subpolar North Pacific. Two complete migrations are made each year between hauling sites and foraging habitats. Seals pup, nurse, and wean young, and breed from December through middle March at the hauling sites, then swim north to forage. They return to haulouts to molt during spring and early summer, then return again to foraging areas. Schedules for migration vary among age and sex categories. When hauled out, elephant seals are concentrated at high density. Hauled seals are easily approached by humans, substantially more so than other land-breeding pinnipeds of North America.

Northern elephant seals have been utilized for food and oil over the centuries by native peoples of North America. Intensive commercial harvests for oil began early in the nineteenth century. Most colonies of seals were severely depleted by 1850, but commercial harvests continued until 1884, at which point the species was considered extinct. Subsequent discoveries of small numbers led to continued harvests by scientific collectors working for museums of natural history. Scientific collecting continued until at least 1911. The total number of surviving seals is thought to have been as low as 20–100 individuals in 1890. At the time harvests finally ended, elephant seals survived only at Isla Guadalupe, west of Baja California, Mexico.

Northern elephant seals numbered approximately 125,000 individuals in 2005. They occupy at least 16 major hauling sites in Mexico and California. In the recent decades at least four new mainland breeding and molting colonies have developed along the central California coast. Population growth has been approximately 6% per year through most of the century. Recent studies indicate a marked lack of genetic diversity at assessed loci, almost certainly a result of the severe population "bottleneck" associated with commercial and museum harvests. Northern elephant seals are not listed as per ESA or RLTS.

The elimination of commercial harvest has allowed northern elephant seals to recover fully from near extinction despite a striking loss of genetic diversity. Most current management concerns for the species involve problems of overabundance rather than rarity. Indefinite survival should be assured as long as harvests and disturbances to habitat can be monitored and controlled.

Scientific Whaling and Marine Mammal Extinction

Whaling in international waters is regulated currently by the IWC, pursuant to the International Convention for the Regulation of Whaling, approved by original member nations in 1946. Although often referenced as "international law," the regulatory authority of IWC applies only to member nations and relies entirely on their voluntary compliance. IWC protocols also include options for member nations to file exceptions to adopted regulations, allowing pursuit of activities contrary to IWC protocols. Several nonmember nations are engaged currently in active whaling.

In 1986 IWC established a moratorium on whaling based on the argument that information on the status and dynamics of whale populations was inadequate for development and application of an effective and informed management strategy. The moratorium was a reflection of the tendency of IWC in the recent decades to adopt more precautionary, conservation-oriented approaches to the regulation of whaling, but was opposed by some member nations. The moratorium remains in effect to the present. In 1988 Japan, an IWC member nation, was granted a “special permit” to allow resumption of whaling, ostensibly for scientific research purposes. The initial request was for an annual quota of 800 whales with an emphasis on minke whales in the southern ocean. The magnitude of the initial quota request drew sharp criticism from a broad range of interested parties and was soon pared to 300 whales. The stated primary intentions of harvest, implemented by the Institute of Cetacean Research in Japan (ICR), were to improve the understanding of interactions of whales with harvested fish stocks and other elements of marine ecosystems. ICR indicated an intention to market meat and other products from whales taken under the special permit once data were obtained from animals killed.

ICR harvested 6778 Antarctic minke whales (*Balaenoptera bonaerensis* Burmeister, 1867) over an 18-year span following receipt of the special permit (Baker *et al.*, 2010). Harvesting also occurred in the western North Pacific region. To date, ICR harvests are known to have included North Pacific common minke whales (*Balaenoptera acutorostrata scammoni* Deméré, 1986), sei whales (*Balaenoptera borealis borealis* Lesson, 1828), Bryde’s whales (*Balaenoptera brydei* Olsen, 1913), sperm whales (*Physeter macrocephalus* Linnaeus, 1758), and Antarctic fin whales (*Balaenoptera physalus quoyi* (Fischer, 1829)), in addition to Antarctic minke whales. The permit remains in effect to the present and the ICR harvest is continuing.

There is no indication to date that whaling by ICR pursuant to the special permit from IWC has directly increased the jeopardy status of any whale population from which animals have been taken. Nevertheless, the ICR harvest has been subject to criticism in several categories. First, there have been persistent arguments that use of lethal take to obtain targeted scientific data is unnecessary, and cannot be justified given the range of alternative methods available to investigate many of the scientific questions identified by ICR. Second, published presentations and interpretations of data from harvested animals have been criticized as inadequate, erroneous, substandard, and redundant relative to information already available in literature. Third, characterization of the harvest as a source of scientific insight has been intensively criticized as a ruse, with the argument that the true purpose is to supply whale products in response to high demand in Japanese markets. Fourth, it has been argued that the harvest should not be permitted for the same reasons that were used to justify the original implementation of the moratorium on whaling by IWC. Fifth, the IWC’s internal process for evaluating results of work under the special permit has been criticized as lacking rigor and compromised by conflicts of interest within the reviewing panels. Finally, there have been concerns that entry of whale meat into open markets will undercut the ability of regulatory protocols, most especially the Convention on International Trade in Endangered Species (CITES), to restrict

trade across international borders for products obtained from species or populations in peril.

International criticism of ICR whale harvests was further stimulated by results of a study published by Baker *et al.* in 2010. Servings of uncooked whale meat were purchased at “sushi” restaurants in California and South Korea and were subject to detailed genetic evaluation. The data were compared with genetic information obtained previously from whales known to have been harvested by ICR pursuant to the special permit. Baker *et al.* concluded that whale products purchased in the restaurants were from animals harvested as per the special permit, with an extremely low statistically based probability of error. The restaurant samples were found to include products from North Pacific common minke whales, Antarctic minke whales, sei whales, and fin whales, as well as material from Risso’s dolphin (*Grampus griseus* (G. Cuvier, 1812)). Baker *et al.* noted that the appearance of whale products in California and South Korea represented evidence of clear violations of CITES.

The published allegations of a CITES violation raise grave concerns regarding the conservation of large whales and the prevention of population- or species-level extinction. The principal concern is that illegal trade across international borders will create an expanded “black market” for whale products and will provide economic incentives for expanded illegal whaling. With the cooperation of Russian scientists, the scope and impacts of illegal harvests in past decades by whalers from the USSR have been well documented and provide a clear indication of the dire conservation consequences of unregulated whaling. For example, as noted previously, illegal Soviet harvests of eastern North Pacific right whales probably had a significant role in driving the population to the threshold of extinction. Illegal harvests of terrestrial wildlife to service the demands of black markets are well known, have placed a number of species into extreme jeopardy, and are extraordinarily difficult to eliminate. It follows that any economic stimulus for covert illegal whaling is a matter of highest concern in the context of marine conservation and the potential for extinctions of the large whales. Thus, continuation of authorized whaling under the special permit should receive the most intensive possible critical scrutiny by IWC. To the maximum feasible extent, political considerations in maintaining the special permit should be superseded by legal and conservation perspectives, most especially the implications of alleged CITES violations.

Global Climatic Trends and Marine Mammal Extinction

Climate change, including ocean warming and acidification, will likely produce substantial negative ecological consequences for marine mammals, although timelines and spatial patterns for impacts are generally unknown and difficult to predict. For marine mammals, most recent discussions linking climate change to extinction risks focus on high-latitude species, especially those that have obligatory ecological links to sea ice (e.g., Moore and Huntington, 2008). Large-scale reductions in high-latitude sea ice cover have been recognized for at least two decades, and there is no evidence to suggest changes in the pattern in the foreseeable future.

We suggest that fifteen Holocene marine mammal species, all known to have obligate ecological relationships with sea ice, are at significant risk of population reduction, possibly including extinction, as global warming continues. Although low- and medium-latitude marine mammals may be able to survive long-term trends in climate by adjusting latitudinal ranges and habitat use patterns, ice-dependent species have no alternative habitat options once projected losses of sea ice reach critical ecological thresholds. Following are ice-dependent species at significant near-term risk as a result of global warming patterns, with an indication of the type of ice typically associated with each species:

Arctic and sub-Arctic pinnipeds (all are phocids except the walrus):

Bearded seal: *Erignathus barbatus* (Erxleben, 1777): pack ice, shorefast ice;

Harp seal: *Pagophilus groenlandicus* (Erxleben, 1777): pack ice;

Hooded seal: *Cystophora cristata* (Erxleben, 1777): heavy pack ice;

Ribbon seal: *Histiophoca fasciata* (Zimmerman, 1783): pack ice;

Ringed seal: *Pusa hispida* (Schreber, 1775): pack ice, shorefast ice;

Spotted seal: *Phoca largha* Pallas, 1811: pack ice;

Walrus: *Odobenus rosmarus* (Linnaeus, 1758): pack ice.

Other Arctic species:

Beluga: *D. leucas* (Pallas, 1776): pack ice;

Bowhead whale: *B. mysticetus* Linnaeus, 1758: pack ice;

Narwhal: *Monodon monoceros* Linnaeus, 1758: heavy pack ice, especially in winter;

Polar bear: *Ursus maritimus* Phipps, 1774: pack ice.

Antarctic species (all phocid pinnipeds):

Crabeater seal: *Lobodon carcinophaga* (Hombron and Jacquinot, 1842): pack ice;

Leopard seal: *Hydrurga leptonyx* (Blainville, 1820): pack ice;

Ross seal: *Ommatophoca rossii* Gray, 1844: medium and heavy pack ice;

Weddell seal: *Leptonychotes weddellii* (Lesson, 1826): shorefast ice.

The list of vulnerable species is longer and more diverse for the Arctic region compared with the Antarctic, correlating with two patterns that may serve as explanations. First, the Arctic marine habitat is proximate to the continental land masses of North America and Asia, possibly influencing the range of options for evolutionary transitions from terrestrial to marine living on an evolutionary scale. In contrast, Antarctic marine ecosystems are well removed from ice-free continental land masses. Second, the Arctic marine environment is an oceanic water mass largely surrounded by land whereas the Antarctic is a land mass fully surrounded by oceanic waters.

Antarctic marine ecosystems are used intensively by blue, fin, and minke whales along with killer whales. However, although reduced ice presence will likely produce negative consequences, fin, blue, minke, and killer whales have more flexible habitat options and higher probabilities of surviving catastrophic reduction of sea ice than the three Arctic cetacean

species with obligatory associations to sea ice. An informative example is provided by geographic changes in foraging patterns of the eastern North Pacific gray whale population in the recent decades. In apparent response to recently documented changes in distribution and productivity of gray whale prey in the Bering Sea, gray whales have expanded their foraging range farther north, with increased presence and feeding in the Chukchi and Beaufort Seas, and farther south, with foraging groups commonly using a number of locations, including the Kodiak Archipelago in Alaska, and sites along the coasts of British Columbia, Washington, Oregon, and northern California. Factors other than climatic shifts may partially explain changes in foraging habitat, including the postulated approach of the population to carrying capacity (see Section "Eastern North Pacific Gray Whale: *E. robustus* (Lilljeborg, 1861)"). However, it is clear that the species can adapt successfully to a shifting prey landscape.

We suggest that polar bears and the southern North Pacific population of spotted seals, the latter dwelling in the Sea of Japan and the northern Yellow Sea in the far western North Pacific region, are likely to be among the earliest of the obligate ice-associated marine mammals to suffer major population reductions as global warming proceeds. The southern spotted seal population is at a lower latitude than other ice seals and may be among the first to experience profound loss of ice habitat. Recent observations indicate that pupping in the population is in transition from pack ice to land, and that dependent pups have been seen leaving haulouts and entering the water before weaning. Both behaviors are abnormal for the species and may indicate the onset of population-scale stresses linked to climatic trends. The southern spotted seal population is listed as "threatened" as per ESA, but is not listed in the RLTS. Pack ice loss rates are also known to be high in Davis Strait (between Greenland and Baffin Island, Canada) and along the eastern coast of Greenland, facilitating vulnerability of resident populations of harp seals and hooded seals.

Polar bears may already be experiencing population-scale stress associated with negative trends in sea ice cover in the Arctic. Polar bears occur in Alaska, Canada, Greenland, Norway, and Russia, with summed populations numbering between 20,000 and 25,000 individuals. Population trend characterizations are difficult to produce for polar bears (see General Factors Hindering Effective Identification and Monitoring of Marine Mammal Populations Vulnerable to Extinction), but there is a general perception that populations are declining in a pattern that roughly tracks observed declines in ice cover. Polar bears in Alaska are listed as "threatened" as per ESA, and global populations are listed as "vulnerable" as per RLTS. Reduction in ice extent poses at least three major ecological problems for polar bears. First, pack ice is the primary habitat for ringed seals, the most important prey species for polar bears in a nutritional context. Thus, reduced ice cover will result in diminished foraging habitat for polar bears, and reduction in prey abundance to the extent that lost ice cover negatively influences ice-dwelling seals. Second, as ice cover dwindles, polar bears will be constrained to increase the amount of swimming required to reach appropriate habitat for foraging. Polar bears must be on the ice surface, rather than in the water, to hunt ringed seals efficiently. Swimming is more costly metabolically than

walking or running on the ice surface for travel. It follows that with declining ice cover, polar bears will be required to expend greater energy per unit of time to reach productive feeding areas, finding smaller and more scattered feeding areas in which to forage on arrival. Finally, significant loss of sea ice will impose increased durations of onshore fasting periods in warmer seasons, possibly beyond metabolic tolerances, causing negative impacts to vital population parameters (e.g., Molnár et al., 2011).

We suggest that other obligate ice-associated species listed above are also likely to experience serious reductions in numbers as global warming proceeds. For these species, sea ice has crucial effects on ecosystem function and prey productivity, on which obligate ice-associated cetaceans and pinnipeds are highly dependent. For the pinnipeds, sea ice is vital as breeding and resting habitat as well. The physical configuration of sea ice has significant effects on key attributes of breeding systems used by ice-dwelling seal species on evolutionary scales, including the intensity of male–male competition, behavioral patterns in territorial defense by males, the level of sexual dimorphism in size, and the degree of polygyny or polyandry. We suspect that drastic reduction or loss of sea ice will overextend the adaptability of the listed species and greatly increase the probability of a collective reduction, perhaps leading to extinctions in some or all cases.

In addition to expanded marine oil exploration and development, already underway, the loss of sea ice in the Arctic region is projected to facilitate a dramatic increase in other forms of human activity, including the introduction of shipping traffic, fishing vessel activity, and other forms of human industrial development in habitats with a largely pristine history. With such actions, a predictable suite of conservation risks will be introduced to ice-dependent Arctic marine mammals, including shipstrikes, fishery bycatch, competition with fisheries for prey in common, chemical contamination, including oil spills, and noise pollution. Disruption to Antarctic ecosystems, with consequent increased risks of extinctions in marine mammal populations, will also emerge with the reduction or loss of sea ice, although likely consequences of the introduction of human industrial presence in the Antarctic are more difficult to predict. Recognizing that projections of ecological effects of climatic trends in middle and low latitudes are unclear, we refrain from specific projections of effects on marine mammals in ice-free regions. We acknowledge that consequences of climate change at lower latitudes could be substantial for marine mammals and likely will test the adaptability of lower-latitude species.

Discussion

Synopsis of Factors and Processes Known to be Facilitating Modern Anthropogenic Extinctions of Marine Mammals

In our review of examples of taxa and populations of marine mammals currently in jeopardy of anthropogenic extinction, we see two major, recurring categories of vulnerability. The first is prolonged excessive harvest, usually for commercial purposes, reducing numbers to a small fraction of pre-exploitation status. In this category we find taxa or populations

from all marine locations on earth, including many that are distant from human population centers. The second is a combination of risk factors strongly linked to a proximate and encroaching human population. The factors include habitat loss or chronic habitat disturbance, incidental taking in fishing gear, and contaminants, as well as directed harvests. The second category primarily includes taxa or populations restricted ecologically to a limited geographic range in near-shore marine or aquatic habitats. Here we consider the vulnerabilities of taxa or populations in the two categories.

The first category primarily involves excessive directed harvest. All species of mysticetes, the larger odontocetes, nearly all pinnipeds, the marine otters, and the polar bear have been hunted extensively at least over the last few centuries, in most cases in order to obtain articles of commerce. Most exploited taxa lack the necessary demographic features to sustain viable populations at the level of harvest experienced. There are two important results. First, such exploitation has often reduced populations to small sizes. Second, populations thus affected require decades or even centuries to recover to levels free of the risks of extinction. Directed, commercial-scale harvests of marine mammals ended for most species during the twentieth century, and many species now are subject to rigorous protection. However, the risk of extinction persists for some reduced populations despite relaxation of harvest activity.

Small populations are vulnerable to any factor that reduces survival or collective reproductive success. Survival and reproduction can be impaired by anthropogenic factors such as contaminants or disturbance to critically important breeding locations, or by natural fluctuations in the biological habitat. Anthropogenic factors should be controllable in principle by the appropriate management actions, but in reality, effective risk management is difficult. Natural fluctuations are effectively stochastic in timing, duration, and intensity, and cannot be anticipated or controlled by any form of management authority. Once marine mammal populations are reduced, they recover slowly and are, therefore, at risk of the damaging effects of anthropogenic damage or natural disturbances over an extended period even under the most rigorous protection. For example, North Atlantic right whales have not been harvested for decades, but prior harvest reduced them to low numbers. Now even low rates of shipstrike mortality or incidental take in fishing gear are adequate to hold the population at a dangerously small size.

The second category involves a group of factors associated with growing human populations in coastal regions, interacting with taxa or populations constrained to life in the coastal zone. Species in this category include the sirenians, river dolphins, and a number of coastal odontocetes and pinnipeds. The essential problem here is that growing human populations produce a suite of effects, each damaging to proximate marine mammal populations. Reduction of the effects often requires a deliberate curtailment of economic enterprise such as fishing, or of institutional infrastructure such as waste disposal, flood control, or the provision of drinking water. The emergent dilemma is the perception by political institutions that there must be a choice between human welfare and the welfare of nearby marine mammals. Our case studies suggest that, given the choice, human cultures of major population centers act in favor of human needs.

Thus, for example, recreational boating activities continue to crowd needed habitat for manatees in Florida despite decades of documentation that manatees do not tolerate powerboat activities, and fishing interests continue to set nets in vaquita habitat despite widespread recognition that incidental take is driving the population to extinction.

Species in our first category have reasonable probabilities of survival. Northern elephant seals escaped the period of vulnerability associated with small population size, and other taxa seem well on their way. Some taxa or populations probably will not persist. Western gray whales and northern right whales, particularly the eastern North Pacific population, will survive the new century only with the most rigorous imaginable protection. We are less optimistic about species in our second category, because their ultimate survival depends on conscious economic restraint by human cultures, and a possible reevaluation of values regarding the survival of marine mammals and other species in habitats also used or coveted by people. Under this premise we anticipate that the vaquita will be the next marine mammal extinction at the species level.

Excessive subsistence harvests, anthropogenic noise, contaminants, oil spills, and depletion of genetic diversity are issues that have at least occasionally been invoked as risk factors for extinction of marine mammals. We find that there are relatively few taxa or populations clearly falling toward extinction as the direct result of any one of these factors. Subsistence harvest by native peoples is without question a serious risk factor for Cook Inlet beluga whales, and may have been a crucial precursor to the extinction of Steller's sea cow. However, the western Arctic bowhead whale population has been growing steadily for years despite regular annual subsistence harvest. Thus, subsistence harvests are manageable risk factors and need not be regarded universally as unacceptable practice. None of the other listed factors are alone causing widespread extinction risk, although there are isolated examples for each. Of greater concern here is the problem of significant effects arising from the interaction of multiple factors. The best-known cases involve mass mortalities that result from disease outbreaks. Such outbreaks often result from immune suppression, which in turn may result from contaminants or from natural disturbances such as the toxic byproducts of certain phytoplankton. Interacting factors often are a problem near human population centers, and are difficult, if not impossible, to manage. Thus, in our view, the danger of many risk factors discussed here is not the direct effect of a single factor, but the synergistic effects of multiple factors that may be less damaging when separated from one another. The inexorable risks posed to marine mammals by human population expansion are further problematic because of inherent uncertainties in population data for many species, confounding efforts to identify and track the status of taxa jeopardized by contact with human populations.

Geographic Regions of Greatest Concern with Regard to Anthropogenic Extinctions of Marine Mammals.

As suggested above, marine mammal taxa and populations constrained to life near human population centers are in general most vulnerable to anthropogenic extinction.

Extinction risks will be greatest where human cultures have the fewest economic options when confronted with the need for restraint in order to solve conservation problems. Such circumstances are most likely in "developing" countries at lower and middle latitudes, where large concentrations of people face ongoing economic shortfalls. Over the next century we anticipate the greatest extinction risks for coastal marine or aquatic marine mammals in southern and southeastern Asia, eastern Europe, central America, and central Africa.

Marine mammals in the southern hemisphere generally should be at lower risk of extinction over the next century than those in the north. Most major human population centers and most cases of coastal habitat degradation occur in the northern hemisphere. However, many southern populations remain small because of past excessive harvests. Thus, distantly located southern taxa and populations will be removed from the risk of extinction only to the extent that all forms of harvest are regulated with extreme caution and conservatism. Moreover, small distant populations are at risk of incorrect conclusions about number of individuals, trend in numbers, or demographic characteristics because of the statistical limitations associated with survey and demographic data that can be obtained only infrequently and at high cost.

General Approaches Toward Minimizing the Rate of Anthropogenic Extinctions of Marine Mammals

Excessive directed harvests have caused more cases of jeopardized marine mammal taxa and populations than any other single factor. Thus the most direct and straightforward approach to the control of extinction risk for marine mammals is a precautionary approach to the concept of marine mammal harvest on a global scale. Fortunately, this is the approach currently adopted by many governments, and by international regulatory cooperatives such as IWC, for some species. In this context we offer three points of caution. First, the protections provided by international treaties and conventions such as the IWC, and by individual governments, do not necessarily extend to all marine mammals. There are high-profile protective protocols, with active ongoing oversight, for the larger cetaceans, some of the pinnipeds, sea otters, and polar bears. Many small cetaceans, some pinnipeds, and some sirenians are not actively or explicitly protected at the national or international level. Second, many of the populations subject to active protection are small in number, and as a consequence will be subject to risks associated with stochastic events, both natural and anthropogenic, for decades if not centuries. Thus, some extinctions are possible because of unequal conservation effort and because the most aggressive protection cannot eliminate all risk factors. Third, the crucial process of detecting trends in small distant populations is so costly that errors are likely in determining which populations are most seriously jeopardized. Thus, despite the best of human intentions, protective effort may be misdirected or inappropriately withheld.

The group of risk factors associated with human population growth will almost certainly cause some extinctions of coastal marine mammals in the current century. Here the outcome is in our view more certain, and the methods of prevention more intractable, than in the simpler cases of small

populations distant from major concentrations of people. Effective protection of imperiled species requires that human cultures forego economic benefits for the good of jeopardized marine mammals. Such sacrifices must extend indefinitely to be effective, given the demographic limitations of most marine mammals. The acceptance of foregone benefits is most needed in cultures least able to accommodate the loss. Cultural acceptance of economic loss motivated by a conservation ethic will require education and reorientation at a level that we find difficult to imagine.

Both evolution and extinction of species have been characteristic features of the history of marine mammal taxa on earth since the early Eocene. Although the anthropogenic loss of species is both regrettable and inevitable in our view, there is no reason to deny that new species will evolve as well. For example, killer whales off Washington and British Columbia occur in three distinctive social configurations, termed “ecotypes”, that correlate with subtle but reliable morphological differences. The different ecotypes have entirely different diets, different acoustic repertoires, and rarely co-occur in space. Some have characterized these patterns as a step in the process of speciation, although there are alternative viewpoints. The human mind can easily perceive extinction but often not speciation as a finite event, because of differing time scales and imprecise definitions of the latter. Thus, we are biased toward greater conscious awareness of extinction than of speciation. Although anthropogenic extinctions should not be accepted without exhaustive attempts at recovery, it is perhaps more pragmatic to view such events as one part of a dynamic process of evolution, rather than as catastrophic failures of human behavior.

Glossary

Allometry How a biological feature is related to body mass; for example, basal metabolic rate varies with body mass raised to the power three-quarters rather than in direct proportion with body mass, so that an animal twice as large requires less than twice the amount of food to supply its metabolic needs.

Graminoids Grasses plus grass-like plants such as reeds and sedges.

Holocene The epoch in time extending from 11,700 years ago, approximately when the last ice age ended, to the present.

Home range The area typically traversed by an animal in meeting its life requirements over some period.

Keystone A species or some other entity (such as a habitat) that has a disproportionate influence on maintaining or influencing a structure, for example, the species composition and functioning of an ecosystem.

Pleistocene The epoch or period in time from approximately 2.5 million to 11,700 years ago, which included a series of glacial advancements or ice ages separated by interglacial periods.

Introduction

In this article, the label “megaherbivore” will be restricted to plant-eating animals attaining a body mass exceeding 1000 kg, that is, a metric ton or 10^6 g, as adults. The label “megafauna” has been widely used to encompass species weighing more than 100 lbs (44 kg), including herbivores and carnivores. This label originates from Martin (1966, 1967) and is somewhat arbitrary. In contrast, there are fundamental distinctions in several features of ecology manifested once a body mass of 1000 kg is surpassed. They concern life history attributes, vulnerability to predation, population growth potential, digestive capabilities, biomass densities attained, vegetation impacts, relationships with humans, and conservation issues, defining “the megaherbivore syndrome” (Owen-Smith, 1988).

Megaherbivores were once far more abundant and diverse than they are today, and occurred on all continents. Especially prominent were elephants and elephant-like beasts falling within the order Proboscidea (Table 1). Numerous members of the Perissodactyla (odd-toed ungulates), including rhinoceroses and their allies, also attained megaherbivore size, along with some of the largest artiodactyls (even-toed ungulates) and edentates (ground sloths). Anthracotheres, possibly ancestral to hippos, also included species within the megaherbivore size range. Several species exceeded the modern African savanna elephant in size. The massively built bronchotherium *Paraceratherium* (formerly known as *Baluchitherium*) attained a shoulder height of approximately 5.5 m and body mass of perhaps 20 tons, and was the largest land mammal ever.

Numerous megaherbivores survived into the late Pleistocene, from 100,000 years ago until as recently as 11,000 years ago, when the last ice age ended (Table 2). They included several species of mammoths and elephants together with allied gomphotheres. Europe formerly housed three species of rhinoceros. Giant ground sloths in several forms occurred within South America and southern North America, whereas a hippo-like notoungulate existed in South America. Within

Australia, a giant wombat-like marsupial attained rhinoceros size.

Extant terrestrial megaherbivores are today confined to Africa and tropical Asia (Table 3). They include the African elephants, recently separated into two distinct species (Rohland *et al.*, 2010); the Asian elephant; four rhinoceros species in this size range; the hippopotamus; and, marginally, the giraffe. The West Indian manatee constitutes the sole marine representative. This life form is now absent in the modern faunas of North and South America, Europe, northern Asia, and Australasia.

The author's doctoral study on the behavioral ecology of the white rhinoceros brought to his attention the common ecological features shared among elephants, hippos, and rhinos, as well as the relevance of these attributes to certain contentious scientific issues. These concerned (1) the causes of the wave of large mammal extinctions that reduced megafaunal diversity through most of the world at the end of the Pleistocene and (2) the dilemmas of conserving the megaherbivores that have survived to the present time. Some paleoecologists regret the impoverishment of the North American megafauna and have advocated replicating the ecological role extinct species played by importing modern counterparts, including elephants (Donlan *et al.*, 2005, 2006; Martin, 2005). Similar proposals have been made for Siberia and Europe (Zimov *et al.*, 1995; Svenning, 2007). Are these proposals crazy, or insightful? The reader must judge for his or herself from the information about the ecology of these largest land mammals presented in this article.

Nutritional Physiology and Dietary Tolerance

Except in deserts and polar regions, vegetation accumulates annually as potential food for herbivores to produce the appearance of a “green world.” Why is so little eaten? Certain ecologists proposed that this was because predators kept the abundance of herbivores well below the level that this food

could support (Hairston *et al.*, 1960). However, much of what appears green is loaded with indigestible fiber and nasty chemicals, so that only a tiny fraction is actually edible (Janzen, 1979). Moreover, during the winter or dry season, most plants cease growth and many shed their leaves, so that very little edible material remains available toward the end of the adverse season (Sinclair, 1975). Herbivores must cope with

food that appears abundant seasonally, but is mostly of low quality nutritionally, especially in the adverse season.

Larger body size brings one fundamental benefit for herbivores. The metabolic rate of animals increases as a function of body mass raised to the power three-quarters, rather than in direct proportion with body size. This allometric relationship means that the specific metabolic requirement for

Table 3 Megaherbivores still extant

Common name	Scientific name	Adult body mass (kg)		Historic distribution	Status
		Female	Male		
African savanna elephant	<i>Loxodonta africana</i>	2800–4000	5000–8000	Africa-wide	Still widespread and locally abundant
African forest elephant	<i>Loxodonta cyclotis</i>	2500	4500	Forested regions of Africa	Declining under hunting
Asian elephant	<i>Elephas maximus</i>	2500–4000	4000–5400	India, Burma, Thailand, Malaysia, Vietnam, Sri Lanka	Locally common but insecure
Hippopotamus	<i>Hippopotamus amphibius</i>	1350–2350	1500–2600	Africa-wide	Abundant
White rhinoceros	<i>Ceratotherium simum</i>	1600–1800	2200–2400	Southern and northeastern Africa	Secure in south, extinct in north
Great Indian rhinoceros	<i>Rhinoceros unicornis</i>	1600	2100	India, Nepal	Restricted to reserves
Black rhinoceros	<i>Diceros bicornis</i>	1000–1300	1000–1300	Most of Africa	Uncommon and endangered
Javan rhinoceros	<i>Rhinoceros sondaicus</i>	1300	1300	Java	Rare and endangered
Giraffe	<i>Giraffa camelopardalis</i>	825–1125	1200–1400	Southern and east-central Africa	Common and secure
West Indian manatee	<i>Trichechus manatus</i>	1600	1600	Florida, Caribbean, northern South America	?

energy and nutrients per unit of body mass diminishes with increasing body size. However, the amount of food an animal can consume per day depends on its gut capacity, which is directly proportional to body size and hence mass. As a consequence, larger herbivores can satisfy their nutritional requirements from lower quality food than can smaller animals (Jarman, 1974). Accordingly, a greater fraction of the vegetation is suitable food to support a megaherbivore than is the case for medium-sized herbivores. This basic relationship contributes toward the repeated tendency for mammalian herbivore lineages starting off small to evolve toward larger body mass over time, culminating in the megaherbivore syndrome. The largest birds like ostriches, emus, and the extinct

moas (in New Zealand) and elephant birds (in Madagascar) are also herbivores, but remain below the megasize threshold.

Digestive physiology contributes further toward dietary tolerance. The cellulose molecules constituting most of this fiber cannot be digested by mammalian enzymes. Hence, microbial fermentation is employed to degrade the fibrous cell walls into fatty acids, which can be used in place of glucose as an energy-yielding substrate. Ruminants within the order Artiodactyla have a greatly enlarged chamber anterior to the true stomach called the rumen, where this fermentation occurs. The foregut location of this chamber also permits these animals to ruminate (or chew the cud) to increase the surface area available to bacterial enzymes. The largest extant

ruminant is the giraffe (*Giraffa camelopardalis*; body mass typically 1200 kg for males and 825 kg for females), which is entirely a browser on the foliage of tall trees, and among wild cattle the gaur (*Bos gaurus*; males typically 940 kg and females 700 kg). Hence, only males and perhaps exceptional females of these two species enter the megaherbivore size range. Among extinct ruminants, the giant Irish elk (*Megaloceros giganteus*) also came close to megaherbivore size, although its exact weight can only be conjectured. Ruminants gain little digestive benefit from growing larger than the 1000 kg threshold, because cattle and wild bovines are capable of digesting almost all of the plant foliage that is potentially fermentable (Demment and Van Soest, 1985; Clauss *et al.*, 2003). The absolutely indigestible fraction consists of cellulose coupled with lignin, the substance of wood. The limitation of ruminant digestion is that especially fibrous plant tissues do not pass readily through the orifices, retaining material in the rumen, so that ruminants can starve despite having a gut full of potential food. Hence, ruminants seek out the more digestible components of the vegetation, such as green leaves, and avoid stem tissues as much as is possible.

All megaherbivores apart from giraffe are nonruminants, mostly relying on fermentation taking place in the hindgut region, specifically the colon and cecum (Langer, 1988). Larger size means that the forage consumed takes longer to pass through the digestive tract, allowing it to be digested more completely. Nevertheless, the inability to chew material further after ingestion limits the digestive efficiency of non-ruminants. Experiments feeding standard diets to zoo animals showed that the extent of fiber digestion achieved by white rhinos was similar to that of medium-sized antelope, but less than exhibited by cattle and wild bovines (Foose cited by Owen-Smith, 1988; Steuer *et al.*, 2010). However, digestive adaptations vary among extant megaherbivores. Elephants show a comparatively rapid passage rate through the gut, similar to that of equids, and digest the forage they eat rather poorly (Clauss *et al.*, 2007a). Hippos ferment forage within an expanded foregut, without the benefit of rumination and rely on prolonged retention to achieve adequate efficiency.

Distinctions in digestive anatomy between grazing and browsing ruminants are underlain by the need to ferment fibrous grass leaves for longer than more succulent tree leaves (Hofmann and Stewart, 1972). Counterpart distinctions in the forage eaten exist among megaherbivores. White rhinos, Indian rhinos, and hippos are mostly grazers. The African savanna elephant and Asian elephant both consume a mixed diet including a substantial proportion of tree leaves, twigs, bark, roots, and fruits as well as grass, thus including some very fibrous material. Black rhinos are mostly browsers and show shorter retention times and hence less efficient digestion than white rhinos. The extinct mammoths appear more specialized than modern elephants for grazing from their den-tition, while the extinct woolly rhinoceros was also mainly a grazer. Among gomphotheres and ground sloths, some species concentrated on grass and others on browse (MacFadden, 2000; Prado *et al.*, 2005).

Differences in capacity to detoxify plant secondary chemicals, which are more prevalent in the foliage of woody plants and forbs than in grasses, also exist (Hofmann, 1989). Black rhino diets contain many plant species with potentially toxic

chemicals, especially stem succulents in the family Euphorbiaceae with milky latex (Loutit *et al.*, 1987; Luske *et al.*, 2009). African elephants, however, reject many woody species readily eaten by ruminants, suggesting that they are less tolerant of plant secondary chemicals. Their special adaptation is a capacity to utilize very fibrous plant parts, such as bark and roots, during hard times, which they extract by bark-stripping, felling, or uprooting trees and shrubs (Owen-Smith and Chafota, *in press*).

However, the digestive adaptations of megaherbivores lead to an elevated dietary requirement for sodium and potassium, as has been established for black rhinos compared with horses (Clauss *et al.*, 2007b). As a consequence of lowered digestive efficiency, the fecal bulk produced per unit of dry matter intake is greater, resulting in a greater loss of these minerals in the feces. This finding fits with observations showing that elephants select waterholes with higher sodium contents (Weir, 1972), and ingest sodium-rich soil, in regions where water supplies are deficient in sodium (Holdo *et al.*, 2002). The elevated requirement for sodium, sparsely present in most plants, could restrict the distribution of megaherbivores. For example, white rhinos were historically absent from the Highveld Grassland region of southern Africa, whereas black rhinos occupy especially the drier savannas and shrublands, where evaporation concentrates salts in soils (Owen-Smith, 1988).

On account of their dietary tolerance, megaherbivores would have been widely distributed through landscapes in the past, just as elephants and rhinos had been in Africa before humans restricted their presence. A much larger proportion of the vegetation would have been consumed and digested via herbivore guts, leaving less to be decomposed more slowly by soil organisms.

Vulnerability to Predation

A second fundamental feature of megaherbivores is that they are effectively invulnerable to predation, except by humans, in the adult stage. This removes a second factor restricting the habitat occupation of smaller herbivores: the heightened risk of being killed in places where predators hunt most successfully. Elephants and rhinos brazenly penetrate areas of dense bush and long grass providing ample cover for ambush predators like lions, whereas grazing antelopes usually avoid closed habitats, however good the forage quality offered. These megaherbivores are also relatively more active at night, when ambush predators are more effectively concealed, than most smaller ungulate species (Owen-Smith, 1988). This helps them to meet their greater quantitative food requirements when food is sparse.

Apart from a few calves, elephants, rhinos, and hippos hardly featured in predator kills recorded in the Kruger National Park (Owen-Smith and Mills, 2008). Giraffes are frequently killed by lions (*Panthera leo*) in Kruger Park, but rarely in Serengeti National Park (Hopcraft, 2010), indicating the transitional status of their body size. Elephant calves are closely protected by their mothers while very young, but become more vulnerable to being predated during droughts when they lag behind the herd (Loveridge *et al.*, 2006).

In Botswana's Chobe National Park, a large pride of lions specialized in killing young elephants near waterholes at night during the late dry season (Joubert, 1986; Power and Compton, 2009). Young hippos constituted a substantial proportion of lion prey in Zambia and Congo (Bourliere and Verschuren, 1960). Attacks by lions on young or near-adult rhinos of both African species have been recorded (Goddard, 1976; Pienaar, 1970; Joubert and Eloff, 1971; Brain *et al.*, 1999), but seem infrequent. Black rhino calves seem especially vulnerable to being killed by spotted hyenas (*Crocuta crocuta*; Hitchins and Anderson, 1983). A substantial proportion of Indian rhino calves are killed by tigers (*Panthera tigris*; Dinerstein, 2003), and tigers are also a threat to Indian elephant calves (Sukumar, 2003).

The close family groups formed by elephants are basically an adaptation to protect offspring from predator attacks. Adult rhinos of all species are generally solitary, apart from mother-offspring pairs, as also are hippos while foraging on land (Owen-Smith, 1988). However, subadult white rhinos associate in groups numbering from two to three animals up to 12 or more, sometimes including an adult female lacking a calf. When threatened, animals in these groups stand with rumps together and horns facing outward in a defensive formation.

Extinct saber-toothed felids had enlarged upper canine teeth seemingly adapted to slice through the tough hides of very large prey, although only the largest species would have threatened adult megaherbivores (Turner and Anton, 2004). Nevertheless, all animals become increasingly weakened with advancing age. Besides killing young animals, these saber-tooths may also have assisted the death of aging megaherbivores. The dwarfing of elephants and hippos that has occurred repeatedly on islands lacking large predators (Simmons, 1988; Stuart, 1991) testifies to the contribution of predation toward promoting large size.

The arrival of humans organized in groups with projectile weapons breached the basic defense that megaherbivores had evolved against predation, that is, standing their ground to ward off the attack. Spears could be thrown, or arrowheads launched, until the wounds inflicted weakened the animal, leading eventually to a kill. Fleeing is now the response most commonly shown by elephants and rhinos when humans are detected nearby, appropriate only for this threat, backed by attacks that are rarely effective against nonhuman predators. White rhinos today still waver uncertainly between standing defensively and fleeing when approached by humans, unless the identification of the intruder is clearly by scent, at which point they head for the horizon (Owen-Smith, 1988). Alarm calls from associated oxpecker birds (*Buphagus erythrorhynchus*) also confirm the presence of a human that cannot be identified by sight by the rhinos, because of their poor vision. The frightening charges commonly made by black and Indian rhinos serve to deter potential human hunters.

Vegetation Transformation and Ecosystem Processes

Digestive tolerance coupled with invulnerability to predation means that the abundance attained by megaherbivores measured as population biomass density (i.e., mass per unit

area) is greater than that manifested by most smaller grazers or browsers. Typically, megaherbivores make up 40–70% of the total herbivore biomass in African savanna ecosystems where their populations have not been decimated by past or current human hunting (Figure 1). Within Kruger Park, reintroduced white rhinos have become the third most abundant herbivore in biomass, after elephants and buffalos. The fertile Serengeti ecosystem dominated by migratory wildebeest appears to be a notable exception, but lacks the white rhinos that were once abundant there as documented by fossilized remains in Olduvai Gorge (Leakey, 1965). The high biomass of African elephants and white rhinos does not seem to be at the expense of other large herbivores (Skarpe *et al.*, 2004; Arsenault and Owen-Smith, 2012). This means that their grazing and browsing impacts are added over and above those of smaller herbivores. About half of all the vegetation consumed passes through the digestive systems of megaherbivores, and the remainder through the guts of all of the remaining large herbivores combined.

The high abundance and physical capabilities of megaherbivores mean that they function as habitat engineers altering structural features of the vegetation. Elephants have substantially transformed savanna vegetation structure, and to some extent the composition of woodlands, through their browsing and breakage of trees (Laws, 1970). Quite large sections of regional landscapes have been changed from tree savanna into open grassland or coppice shrubbery, depending on soils and rainfall (Bell, 1981; McShane, 1989; Western, 2007). Intense fires burning the grass layer contribute to the lack of regeneration by trees (Dublin *et al.*, 1990; Holdo,

Figure 1 The contribution of megaherbivores (dark shade) to total large herbivore biomass in relatively intact African ungulate assemblages. Uganda is represented by combined data for Queen Elizabeth and Murchison Falls national parks.

2007), but exclosure plots show the overriding effects of elephants both in Uganda (Smart *et al.*, 1985) and in Kruger Park in South Africa (Levick and Rogers, 2008; Levick *et al.* 2009). Stands of coppicing shrubs cultivated by elephants through breaking leader shoots have been labeled “browsing lawns” (Fornara and du Toit, 2007; Owen-Smith, 2003; Makhabu *et al.*, 2006), by analogy with the grazing lawns described later, implying enhanced food availability for the elephants. Vulnerable plant species may become restricted to steep slopes or places far from water where they are less likely to be encountered by foraging elephants (Edkins *et al.*, 2007). Asian elephants have somewhat less impact on the woodlands and forests to which they are largely confined, but may nevertheless depress the abundance of favored understory trees in deciduous woodlands (Sukumar, 2003). Black rhinos can topple succulent euphorbias (Luske *et al.*, 2009). Heavy browsing or other damage to plants by black rhinos and giraffes can restrict the distribution of sensitive tree species (Bond and Loffell, 2001; Wiseman *et al.*, 2004). Carbon isotope studies indicate that in earlier times, African savanna elephants subsisted largely on grass, suggesting a scarcity of trees through much of their range (Cerling *et al.*, 1999). However, the lack of trees may also have been promoted by the cooler temperatures and lower atmospheric CO₂ levels prevalent during the Pleistocene (Bond *et al.*, 2003).

Grazing impacts by white rhinos have converted areas formerly supporting tall grassland in Hluhluwe-iMfolozi into a mosaic of short grass areas or “grazing lawns” interspersed with taller grass patches (Owen-Smith, 1988; Waldram *et al.*, 2007). Hippos likewise ‘cultivate’ extended grazing lawns near the pools where they seek day-time refuge (Olivier and Laurie, 1974). Grazing by hippos near rivers and by white rhinos more widely may suppress the spread of fires, facilitating the regeneration of the trees damaged by elephants. Grazing lawns provide more nutritious grasses, attracting concentrations by smaller grazing ungulates (Verweij *et al.*, 2006; Arsenault and Owen-Smith, 2012).

Even in Africa, no area today bears testimony to the ultimate state of the landscapes transformed by the combined impacts of both browsing and grazing megaherbivores at their potential saturation densities. Hippos as well as elephants attained high densities in Queen Elizabeth National Park in Uganda, but their grazing impacts are confined to the vicinity of water rather than affecting the broader landscape (Lock, 1972). Reintroduced white rhinos remain well below their former densities outside the Hluhluwe-iMfolozi Park, and the elephant population reintroduced there is still growing.

During Pleistocene times when megaherbivores of many species were abundant, areas of North America today covered by fairly uniform forests showed a mix of conifers, broadleaf hardwoods, and graminoids, suggesting a parkland mosaic (Wright, 1984; Gill *et al.*, 2009). The prairie grassland that today predominates in western America has no earlier counterpart. The grassy steppe tundra that once stretched from Alaska through Siberia into northern Europe has been replaced by the dense assemblage of shrubs, mosses, and bogs that characterizes the modern tundra (Zimov *et al.*, 1995). Former associations of animal species were quite disparate compared with modern assemblages: Grazing mammoths, equids, and bison coexisted alongside browsing mastodons,

ground sloths, tapirs, and deer, plus mixed feeders like caribou and muskoxen, in the Appalachian region (Guilday, 1984). The mosaic interspersed of vegetation types of the Pleistocene has become transformed into the zonal vegetation bands of today, largely climatically controlled (Guthrie, 1984).

In northwestern Europe, pollen and animals indicative of open vegetation suggest that, even during the last interglacial, grassy meadows were quite common in the landscape, compared with the current predominance of closed forest in areas undisturbed by humans (Svenning, 2002; Vera *et al.*, 2006). Even today, grazing and browsing by cattle and horses suppress tree regeneration locally, thereby maintaining grassy gaps and promoting a cyclic succession pattern (Olff *et al.*, 1999). The complete disappearance of the grassland steppe that prevailed through northern Europe, Siberia, and Alaska during glacial conditions has been related to the loss of megaherbivore impacts maintaining the open soil cover, and thereby restricting permafrost development (Zimov *et al.*, 1995).

Through opening the forest cover, megaherbivores facilitate the penetration of fire, which further modifies these habitats (Svenning, 2002; Gill *et al.*, 2009). Their grazing impacts suppress the spread of fires within grasslands, facilitating tree and shrub establishment. In this way they contributed to vegetation formations prevalent during the Pleistocene that have no modern analog (Wright, 1984).

The vegetation changes induced by megaherbivores also facilitate the coexistence of smaller, more selective grazers and browsers, by bringing more of the vegetation within the height range favored by the latter (Rutina *et al.*, 2005). Moreover, regenerating plant parts are fundamentally more nutritious than the components removed (Makhabu *et al.*, 2006). The overall energy flow through the large herbivore biomass may thus be greatly enhanced by the presence of megaherbivores, at the expense of the amount recycled more slowly through termites and other soil organisms, or incinerated by fire. Hence, megaherbivores may play a ‘keystone’ role in maintaining both habitat productivity and a diversity of other species (Owen-Smith, 1987, 1989).

Life History Patterns and Population Regulation

Megaherbivores live longer, attain reproductive maturity later, have lengthened gestation periods, and have more prolonged intervals between successive births, than smaller species, because of the allometric dependency of metabolic rates on body size (Owen-Smith, 1988). Specifically, the time taken for these events to occur generally lengthens as a function of body mass raised to the power one-quarter. Elephants of both species can survive up to 65–70 years (Moss, 2001; Sukumar, 2003), whereas the potential longevity of rhinos and hippos is 45–50 years (Owen-Smith, 1988). The highest recorded age for a giraffe is 28 years. Aside from primates and cetaceans (whales and dolphins), other mammals do not survive much longer than 20 years.

Most crucially, gestation periods of megaherbivores generally exceed one year, the exception being the hippo with a gestation time of only 8 months. Consequently, intervals between successive births span two or more years, even for hippos, and hence become partly decoupled from the annual

seasonal cycle. The shortest birth intervals recorded for elephants and rhinos fall close to the allometric trend extrapolated from smaller species, but observed mean birth intervals are somewhat longer (Figure 2(a)). Thus, although megaherbivores have the capacity to produce offspring as fast as

Figure 2 Allometric trends among large mammalian herbivores in (a) interval between births and (b) age at first conception. Circles represent the population averages; lines below indicate minimum records. Trend lines shown have a slope proportional to body mass raised to the power three-quarters.

allometric constraints allow, in practice they tend to reproduce more slowly in response to nutritional shortfalls.

A similar pattern exists with regard to the age at first conception, but in this case even the youngest ages recorded for elephants and rhinos tend to be greater than would be expected from allometric extrapolation (Figure 2(b)). Elephants take an especially long time to reach reproductive maturity, perhaps for social reasons.

Ungulates below megaherbivore size mostly reproduce annually, with offspring born at the time of the year when conditions are most favorable nutritionally for the elevated demands of late gestation and lactation. Among megaherbivores, births are spread through the year, but with a peak in the monthly frequency of conceptions leading to a subsequent peak in births. African elephants, with a 22-month gestation, show a concentration of births early in the wet season, derived from a conception peak 2 months into the wet season (Wittemyer *et al.*, 2007). Asian elephants kept in captivity in India and Myanmar have a birth peak extending into the early dry season, indicating a conception peak during the monsoon rains (Sukumar, 1989). Indian rhinos in Nepal show a similar seasonal concentration of births to these elephants, despite having a shorter gestation (Dinerstein, 2003). However, white rhinos, black rhinos, and giraffes, with gestation times of 15–16 months, exhibit birth peaks during the early part of the dry season, following conceptions concentrated during the rains. Hippos, in contrast, have a conception peak in the early dry season leading to births during the rains. This flexibility in reproductive seasonality is probably an outcome of the spread through the year of critical nutritional demands preceding mating, after birth and following weaning.

Slowed reproduction restricts the proportional rate at which megaherbivore populations can increase. The maximum growth rate for an African elephant population is approximately 6.5% per year, assuming minimal mortality, whereas for a white rhino population, the maximum sustainable rate is 9% per year (Owen-Smith, 1988). Annual population increases may exceed these levels, due to synchronized pulses in reproduction and irregularities in the population structure. Realized population growth rates in the long term are likely to be somewhat slower than the maximum potential rate due to environmental variation and resultant mortality, especially among calves (Moss, 2001).

The pattern of density dependence in the population growth rate shown by megaherbivores may also deviate somewhat from that shown by less large mammals. Mammal populations that are nutritionally limited may experience little reduction in their growth rates until some threshold density has been exceeded (Fowler, 1987). Megaherbivores take this pattern to extremes, as has been documented for whales (Chapman, 1981), and show little response to increasing density until their abundance is quite close to the habitat capacity (Figure 3). This explains the lack of signs of density dependence by recovering populations of African elephants and white rhinos that has perplexed some observers (Owen-Smith *et al.*, 2006; Gough and Kerley, 2006). Nevertheless, substantial delays in the age at first reproduction and lengthening of birth intervals have been recorded for African elephants crowded at high densities within protected areas by human settlements and hunting outside (Laws and Parker,

Figure 3 Relationship between the population growth rate and the population size expected for megaherbivores, showing delayed onset of the density-dependent reduction in the relative growth rate (dotted line), and the corresponding right-skewed recruitment curve (i.e., the numerical growth increment; solid line).

1968). Asian elephants, largely confined to forests by human settlements and cultivation, show population growth rates only slightly positive through similar reproductive responses (Sukumar, 1989, 2003). In the Hluhluwe-iMfolozi Park, the shrinking black rhino population showed greatly retarded reproductive rates compared with the expanding white rhino population in the same park, in response to deterioration in its habitat (Hitchins and Anderson, 1983; Owen-Smith, 1988). Indian rhinos in Nepal exhibit substantially longer calving intervals than expanding white rhino and black rhino populations in Africa, although the age at first reproduction differs little (Dinerstein, 2003).

Megaherbivore populations are also less responsive to yearly variation in rainfall conditions than annually breeding ungulates. Elephant population trends are affected little in most drought years, except that conceptions tend to be deferred, leading to fewer calves being produced a year or two after the drought. This response can generate annual peaks and troughs in births (Moss, 2001). Nevertheless, elevated mortality among calves does occur during extreme droughts (Conybeare and Haynes, 1984; Dudley *et al.*, 2001; Foley *et al.*, 2008). Contributing to the heightened calf mortality is the increased daily distance that animals must travel between food and water (Young and van Aarde, 2010), increasing their susceptibility to predation (Loveridge *et al.*, 2006). An exceptional die-off of elephants occurred in Tsavo East National Park in Kenya when severe drought conditions persisted through two successive years in this semiarid region, affecting adult females as well as their offspring (Corfield, 1973). Total mortality amounted to approximately 20% of the population and was concentrated near rivers in the driest region of the park. Predisposing this mortality was the compression of elephants into the park by hunting activities outside (Myers, 1973; Parker, 1983).

Despite the drought conditions prevalent in the Hluhluwe-iMfolozi Park during the late 1960s, the white rhino population continued to increase at its maximum potential rate, perhaps because less rain meant that the grass produced was more nutritious (Owen-Smith, 1988). Hippos are somewhat more susceptible to drought-related mortality than other

megaherbivores because of their grazing restriction to the neighborhood of rivers, where forage becomes most severely depleted. Hippos correspondingly show shorter calving intervals and earlier reproduction than other megaherbivores, enabling them to recover faster from population crashes.

Elephants have the capacity to move widely to avoid locally adverse conditions, when not restricted by human settlements or fences. Seasonal home ranges typically encompass 500–1000 km² during the dry season, when access to surface water may serve as a restriction, expanding to approximately 2000 km² in the wet season, in drier savannas, but tend to be generally smaller in wetter savannas (Young *et al.*, 2009). In semidesert areas, annual ranges traversed by elephants may extend over much as 6000 km² for females and 12,000 km² for males, although only a fraction of this area is actually utilized (Leggett, 2006). During the wet season, elephant herds concentrate opportunistically in places where local rainfall has resulted in greening of the vegetation (Loarie *et al.*, 2009). Home ranges documented for Asian elephant herds cover 100–800 km² (Sukumar, 2003). Within the high-density Hluhluwe-iMfolozi population, female white rhinos moved through overlapping home ranges encompassing 10–20 km², whereas males occupied much smaller discrete territories (Owen-Smith, 1975). Larger home ranges of up to 90 km² have been recorded for white rhinos elsewhere (van Gysegem, 1984; Pienaar *et al.*, 1993). Black rhinos home ranges are typically under 50 km², but may expand to as much as 500 km² in desert regions (Owen-Smith, 1988). Home ranges occupied by Indian rhinos are similar in size to those of the African species. Giraffe home ranges typically cover approximately 100 km², but may be as large as 500 km² in dry regions.

More persistent dispersal movements contribute to the longer term redistribution of elephant populations, responding to changing water as well as food resources (Laws, 1969; Chamaille-Jammes *et al.*, 2008; van Aarde and Jackson, 2007). The regional population of almost 150,000 elephants spread through northern Botswana, western Zimbabwe, eastern Caprivi, and adjoining regions of Angola and Zambia has been increasing in numbers, but not in density, indicating dispersal outward (Junker *et al.*, 2008). The growth of the elephant population within Kruger Park has also slowed as animals moved into areas to the east and west, following the removal of border fences to establish the Greater Limpopo Transfrontier Park. White rhinos showed evidence of dispersal from the high-density core region into outlying areas by subadult animals of both sexes, along with some mature males (Owen-Smith, 1988). Hippos have also been observed transferring between water bodies in response to changing conditions.

Disease has not had much impact on the population dynamics of elephants and rhinos, although white rhinos relocated into East Africa are vulnerable to infection by trypanosome blood parasites causing sleeping sickness in humans. An unusual situation exists in Namibia's Etosha National Park, where periodic mortality from anthrax has stabilized elephant numbers (Lindeque and Turnbull, 1994). However, hippos have been subject to outbreaks of anthrax in the crowded pools where they seek daytime refuge (Wafula *et al.*, 2007).

Stabilization of African elephant populations is likely to come about mainly through reproductive changes, coupled

with episodic mortality mostly among calves during drought years, plus perhaps some predation (Owen-Smith *et al.*, 2006; Wittemyer *et al.*, 2007; Trimble *et al.*, 2009). The robust growth rates shown by most elephant populations not subject to poaching may be a reflection of the exceptionally favorable, low-density conditions that these animals have experienced from birth onward. Cohort effects, whereby animals born under adverse conditions show lower survival and reproductive success throughout their lives (Lindstrom and Kokko, 2002), may come into play at a later stage as populations approach the habitat capacity. Whether regulating processes can operate effectively within the confinements of protected areas is a leading conservation issue.

It is the slow population growth potential of megaherbivores that makes them so susceptible to predation on adults imposed by humans. It also takes longer for their populations to recover after having been reduced. However, this did not make such large animals especially vulnerable to extinction in the past, because of their delayed or threshold density dependence, robust dependence on a wide range of food resources, and capacity to range widely to avert the effects of local droughts or other adverse conditions. Hence, megaherbivores represented an extremely successful life form, until modern humans armed with effective weapons arrived on the scene.

Late Pleistocene Extinctions

The distinctive features of the ecology of megaherbivores are fundamental for explaining the causes of the wave of extinctions that greatly reduced large mammal diversity through most of the world toward the end of the Pleistocene. The crucial features of these extinctions are (1) the strong bias toward larger mammals, which is distinct from all previous extinction episodes, and (2) the differences in timing in different regions of the world, meaning that there is no consistent climatic relationship (Owen-Smith, 1987; Alroy, 1999; Carrasco *et al.*, 2009).

In the late Pleistocene, all megaherbivore species weighing more than 1000 kg, and 80% of macroherbivores in the size range 100–1000 kg, were eliminated throughout all continents except Africa and tropical Asia (Figure 4). Around half of the species weighing between 10 and 100 kg disappeared from North America and Australia, but few losses in this size range occurred in Eurasia and South America. Extinctions of carnivores and scavenging birds occurred along with their herbivore prey (Martin, 1967), and in Australia, giant emu-related birds vanished along with the marsupial mammals (Flannery and Roberts, 1999). Africa lost the last of the grazing *Elephas iolensis* in Tunisia approximately 34,000 years ago (Todd, 2005). Four genera of macroherbivores also became extinct in Africa approximately 10,000 years ago: the antlered giraffe *Sivatherium*; the giant buffalo *Pelorovis*; the giant hartebeest *Megalotragus*; and the giant warthog *Metridiochoerus*.

In tropical Asia, the elephant-like *Stegodon* disappeared approximately 11,000 years ago. In Europe, the last recorded date for the straight-tusked elephant *Palaeoloxodon antiquus* was approximately 40,000 years ago, whereas two rhinoceros species vanished approximately 20,000 years ago (Stuart, 1991, 2005). The woolly mammoth and woolly rhino

persisted in northern Europe and Siberia until as recently as 11,000–10,000 years ago, and, in dwarfed form, on Wrangel Island until 3700 years ago (Vartanyan *et al.*, 1993; Orlova *et al.*, 2004). In North America, the major pulse of megafaunal extinctions occurred within a narrow time window between approximately 12,500 and 11,500 years ago (adjusting radiocarbon dates reported by Stuart, 1991). Dwarfed mammoths persisted in islands off California, and dwarfed ground sloths in the Caribbean, until somewhat later. In South America the extinction wave apparently intensified slightly earlier, between 14,000 and 11,000 years ago (Barnovsky and Lindsey, 2010). The gomphotheres *Cuvieronius* and *Haplomastodon* were last recorded in Chile and Venezuela, respectively, between 14,000 and 13,000 years ago, whereas the giant ground sloth *Megatherium* persisted in Argentina until perhaps as late as 8500 years ago. In Australia, the extinction wave began shortly after 50,000 years ago (Bowler *et al.*, 2003).

In both North and South America, the timing of most extinctions was closely associated with the Cold Reversal between 11,200 and 13,500 years ago, an abrupt cooling interlude interrupting the warming trend associated with the transition from the Pleistocene into the Holocene (Barnovsky *et al.*, 2004; Barnovsky and Lindsey, 2010). There was no consistent relationship with the timing of climate change elsewhere, and extinctions had not been a feature of previous glacial–interglacial transitions, despite temperature shifts similar to those ending the Pleistocene. Species in the megaherbivore size range should be least vulnerable to climatic influences on habitat conditions, because of their wide food tolerance and broad distributions.

However, a consistent association is apparent between the regional timing of the extinctions and the appearance of modern humans in these places (Burney and Flannery, 2005; Lyons *et al.*, 2004). *Homo sapiens sapiens* moved out of Africa into parts of the Middle East between 120,000 and 80,000 years ago, and dispersed from there along a coastal route to reach Australia by 50,000 years ago (Finlayson, 2005). Extinctions of marsupial mammals and emu-related birds followed shortly after the colonization of Australia by the ancestral Aborigine people (Miller *et al.*, 1999; Roberts *et al.*, 2001; Bowler *et al.*, 2003). Modern humans had spread northward into central Eurasia shortly after 50,000 years ago, but were forced back into more southerly regions during the glacial maximum approximately 20,000 years ago. Thereafter their range expanded through northern Europe and Siberia into North America by 15,000 years ago, to reach the southern tip of South America soon thereafter (Goebel *et al.*, 2008). More primitive humans represented by *Homo erectus* had been present as far north as Georgia and China by 1.7 million years ago, and persisted in the Far East until as recently as 30,000 years ago, without any apparent impact on the large mammal fauna. Neanderthal people (*Homo sapiens neanderthalensis*) occupying Europe between 450,000 and 28,000 years ago were inhabitants of Mediterranean woodlands rather than more northern steppe environments (Finlayson, 2005). Modern humans displacing them had a more gracile morphology adapted for endurance running, which facilitated their expansion into the mammoth steppe.

Megaherbivores that had evolved in the absence of humans outside of Africa and tropical Asia would most likely have

Figure 4 Extent of species extinctions during the late Pleistocene for large mammalian herbivores within different body size ranges among the continents. Stippling at bottom indicates still extant species; wavy line indicates species that went extinct.

responded to threatening humans as they did to other predators, by standing defensively, being too slow moving to escape by fleeing (Berger *et al.*, 2001). They would thus have been sitting targets for skilled groups of human hunters, even if the latter were armed only with stone-tipped spears or arrows. The protein provided, preserved in snow, could have been crucial in enabling human groups to subsist through frigid winters in high northern latitudes in Eurasia and North America. Modern elephants and rhinos have evolved aggressive responses from their long association with humans, deterring hunters until improved weapons reduced the risk.

Megaherbivore populations have limited capacity to sustain predation, especially if imposed across all age classes as would have been the case for human hunters. As the proportional harvest approached the maximum population growth potential, populations would have gone into progressive decline, exacerbated by the right skew in the recruitment curve (Figure 3). "Allee effects," manifested through a reduction in the potential growth rate with diminishing density, may have contributed further to a slippery slide toward extinction (Owen-Smith, 1999). Extirpations especially of the megaherbivores became inexorable once humans had built up sufficient numbers (Alroy, 2001). The macromammal types that went extinct tended also to have slow reproductive rates (Johnson, 2002). Nevertheless, predators normally switch to hunting alternative prey species once more favored species become sufficiently rare, thereby averting the extinction of their prey. Humans are unusual in being omnivores as well as effective hunters, and thereby able to subsist on plant food while they continue to hunt large mammals to augment their diet. Climatic shifts may have contributed to the reliance of humans on hunting at a time when crops and wild plants became less dependable.

Around this time the mosaic interspersed of woodland and meadow that typified Pleistocene vegetation patterns became replaced by the broad expanses of uniform forest and extensive grassland persisting into modern times (Guthrie, 1984; Johnson, 2009). Fungal spores typical of large mammal dung fade out rapidly after 14,000 years ago in eastern North America, followed thereafter by a rise in charcoal, indicating extensive fires, together with greater representation of hardwood tree pollen (Robinson *et al.*, 2005; Gill *et al.*, 2009). Last recorded dates of Columbian mammoths after 10,000 years ago fall either in the prairie region along the Canadian border or in the arid region near the Mexican border, where more open conditions remained (Agenbroad, 2003). Some woolly mammoths may also have persisted in Alaska after 10,000 years ago (Haile *et al.*, 2009). Extinctions of numerous large mammals were closely associated with human arrival in the pampas of Argentina and Uruguay and in Patagonia, although elsewhere in South America, humans and large mammals apparently coexisted for several thousand years (Barnovsky and Lindsey, 2010).

The vegetation changes that occurred at the end of the Pleistocene cannot be related solely to climate, because large herbivore impacts and fire also substantially modify vegetation structure and composition (Owen-Smith, 1987; Bond, 2005). In Siberia, there are indications that areas of open steppe-tundra persisted through previous interglacials, but became entirely replaced by boggy tundra after the end of the last ice age (Sher, 1997, reported by Stuart, 2005). The

megafaunal extinction by human hunting could have played as great a role as the climate shift in this radical vegetation transformation from graminoid to shrub and moss dominance (Zimov *et al.*, 1995; van der Wal *et al.*, 2004). As noted earlier (*see* Vegetation Transformation and Ecosystem Processes), disturbance by megaherbivores promotes not only structural vegetation diversity but also greater vegetation productivity, at least in the form of regenerating tissues most supportive of smaller herbivores. Hence, deterioration in habitat conditions for macroherbivores may have followed the elimination of megaherbivores by human hunters, making these other species also more vulnerable to hunting pressure, especially at a time when suitable habitats were potentially shifting in location in response to climate change. However, this "keystone herbivore" hypothesis (Owen-Smith, 1987) does not apply in Australia, where a single, rather minor megaherbivore was lost and the use of fire by aboriginal people has been emphasized as playing a major role in the megafaunal extinctions (Bowman, 1998). Within Africa, the disappearance of the grazing *E. iolensis* earlier in the Pleistocene could have been a consequence of widening use of fire by humans, depleting forage during the dry season bottleneck.

Hence, megaherbivores played a central role in the late Pleistocene extinctions, both through being the animal type most susceptible to extinction by human hunters and by contributing through their demise to the vegetation changes that ensued. Their broad dietary and habitat tolerance negates claims that climatic factors were primarily responsible for the extinction wave affecting primarily large mammals. Nevertheless, extreme climatic conditions could have contributed to the timing of the extinctions in North and South America, through increasing human dependency on hunting, rather than directly through vegetation changes (Koch and Barnovsky, 2006).

Recent Human Impacts

Human hunting of the megaherbivores that survived the late Pleistocene extinctions has expanded in modern times. Trade in ivory was initiated by Greeks and Phoenicians around 800 BC, initially exploiting African elephants then still extant in Syria and Asian elephants in India, although later the source shifted to North Africa (Spinage, 1994). The Roman Empire dominated the demand for ivory during the early few centuries AD, but as elephants disappeared from North Africa, the supply became transferred to East Africa and India. By AD 900, Arab traders were importing ivory from East Africa into India and China because Asian elephants had become scarce. During the seventeenth century, Portuguese traders became involved in the ivory traffic, initially in West Africa, extending later to East Africa and southward, closely linked to the slave trade. European hunters played a major role during the nineteenth century, making a living largely from ivory and supplying guns to local people to increase the supply. The amount of ivory leaving Africa was estimated to be approximately 800 tons per year by the late nineteenth century, leading to the elimination of elephants through much of eastern and southern Africa, as reported by Spinage (1994). In South Africa, a few herds survived in forests of the Southern Cape and two or three herds in the region

adjoining Mozambique that became the Kruger Park. Elephants disappeared from Botswana and most of Zimbabwe and Namibia. Elephants are still killed for their ivory today, despite the international ban on trade, so that their numbers north of the Zambezi River continue to shrink. South of the Zambezi, elephant populations have grown to abundance levels widely regarded as excessive. The ivory trade fell less heavily on Asian elephants for the simple reason that females of this species lack tusks. Although male elephants are killed for their ivory, this has less effect on populations than the slaughter of African elephants encompassing both sexes.

Hunting activities during the nineteenth century included rhinos, with horns traded for various purposes (Selous, 1899). White rhinos were abundant throughout the savanna region south of the Zambezi River early in the nineteenth century, but by the end of this century had been extirpated everywhere save for perhaps 50 animals in the newly proclaimed Umfolozi Game Reserve (the original name), and a few survivors in a remote region of Mozambique (Owen-Smith, 1988). The existence of northern subspecifically distinct white rhinos was discovered only in the early twentieth century to the west of the Nile River, but these animals have recently become effectively extinct in the wild. Black rhinos, secluded in bushy habitats, survived somewhat better, and their elimination through most of Africa took place during the twentieth century largely as a result of the expanding demand for rhino horns in the Far East.

A peculiar feature of the distribution of the white rhino is its historical absence from a broad region of central and eastern Africa, where associated grazers and browsers remain abundant. The white rhino is among the most common species found in Pleistocene fossil deposits in Olduvai Gorge and elsewhere (Leakey, 1965). Teeth found in Kenya and rock engravings in Algeria suggest that white rhinos survived in eastern and northern Africa until merely a few thousand years ago (Lang, 1923; Hooijer and Patterson, 1972). Since habitat conditions seem quite suitable through much of the distribution gap (confirmed by successful reintroductions of the species), it seems likely that white rhinos were eliminated from this region through hunting by early Bantu-speaking people moving from central Africa with effective spears due to their Iron Age culture. By the time these people had colonized southern Africa by AD 1000, they had become cultivators and pastoralists and no longer dependent on wildlife for protein.

More recently, the distribution of elephants and rhinos has become restricted by expanding human settlements and continuing, although largely illegal, hunting. The formerly continent-wide distribution of both African savanna and forest elephants is now fragmented, whereas Asian elephants have become narrowly restricted to woodland and forest patches because of the preemption of more open areas by people. Rhinos have become confined almost entirely to protected areas. Hippos, although secure in their aquatic refuges, and giraffes, less of a target for hunters, remain widespread in Africa, although the hippos that once resided in southern Europe have disappeared.

Conservation Dilemmas

The conservation problems associated with megaherbivores are acutely manifested with respect to both elephants and

rhinos. Throughout eastern Africa, widening poaching for ivory has greatly reduced elephant numbers, whereas black rhinos have been hunted almost to extinction for their horns. Illegally traded ivory is currently coming largely from forest elephants in central African countries. However, in southern Africa, elephant numbers have grown under effective protection to a situation where progressively worsening consequences of their vegetation impacts are feared (Whyte, 2001; Mosugelo *et al.*, 2002), and their range expansion is exacerbating conflicts with people (O'Connell-Rodwell *et al.*, 2000; Sitati, 2007). Numbers of white rhinos have recovered to levels allowing hunting to be permitted as a legitimate activity outside of protected areas, and even black rhinos are approaching this level in some places. This has led to a conflict in conservation policy within Africa with regard to culling and concerning the international ban on any trade in products. Meanwhile, Asian countries retain only small remnants of their elephants and rhinos, thus fully supporting trading bans.

However, it was in Uganda that culling of elephants for broader conservation reasons was first undertaken in 1965, following the development of high concentrations within Murchison Falls National Park and the consequent woodland disappearance; 2000 elephants were killed (Laws and Parker, 1968). Proposals to reduce elephant numbers in Kenya's Tsavo National Park for similar reasons were blocked by sentiment against lethal intervention. Consequently, nearly 20% of these elephants died during severe drought conditions persisting through two successive years, with numbers reduced further by rampant poaching of the survivors.

In 1966, culling of elephants was initiated in Kruger National Park in South Africa (Pienaar, 1983) and Hwange National Park in Zimbabwe (Cumming, 1981), following observations of worsening vegetation damage as elephant populations increased (van Wyk and Fairall, 1969), and shortly thereafter extended to other parks in Zimbabwe and Luangwa Valley in Zambia (Hanks, 1969). The Kruger population was maintained at a density of one animal per square mile (0.4 per km²), initially as a precautionary measure but later routinely, through the elimination of approximately 400 elephants annually until 1994, when animal rights groups challenged the scientific justification for this action (Owen-Smith *et al.*, 2006). Culling was then suspended, apart from some live removals, while a national policy review took place. The framework for this assessment concerned broader objectives for biodiversity conservation within protected areas. Meanwhile, elephant numbers within Kruger Park have doubled, and park managers remain worried about the ecological consequences of the continued growth of elephant populations, not only in Kruger Park but also within smaller wildlife reserves in South Africa.

Within Hwange National Park, the ceiling elephant density was set at one animal per square kilometer (Cumming, 1981). After annual culling had failed to hold the population at this level, 10,000 elephants were killed during 4 years between 1983 and 1986. After this intervention was suspended for logistic reasons, the elephant population grew toward a total of approximately 40,000 animals (almost three elephants per square kilometer), at which size it appears to be stabilizing through movement between the national park and adjoining

areas (Chamaille-Jammes *et al.*, 2008). Within Botswana, proposals were made to cull elephants once numbers in Chobe National Park and adjoining regions exceeded 50,000 within an overall range of 100,000 km². This policy was not implemented because of logistic, financial, and tourism obstacles. Furthermore, a coordinated set of studies failed to establish any ecological justification for culling along the Chobe riverfront, despite the high elephant concentration there (Skarpe *et al.*, 2004). The elephant population centered on Botswana currently numbers almost 150,000 animals, dispersing increasingly into adjoining regions of Namibia, Zambia, and Angola (Junker *et al.*, 2008). Culling merely to cap this population seems logistically impractical, because this would entail the killing of several thousand animals annually, indefinitely, without alleviating the vegetation impact.

Notable areas regarded as devastated by overabundant elephants include Tsavo East and Amboseli National Parks in Kenya and Chobe National Park in Botswana. In Tsavo, elephants transformed *Commiphora* shrubland into open grassland over a large area, reduced umbrella thorn trees (*Acacia tortilis*) to one-third of their former abundance, and almost eliminated baobab trees (*Adansonia digitata*; Leuthold, 1977). Browsers such as lesser kudu (*Tragelaphus imberbis*) and genuk (*Litocranius walleri*) declined in abundance, but grazers like zebra (*Equus quagga*) and oryx (*Oryx gazelle*) increased (Parker, 1983). Following the drastic reduction of the elephant population by poaching, the vegetation has largely recovered (Leuthold, 1996) and no animal populations suffered (Inamdar, 1996). Along the Chobe River, the extent covered by woodland was reduced from 60% to 30%, that covered by shrubland expanded from 5% to 30%, and the tall riparian woodland largely disappeared, following the buildup of high local concentrations of elephants (Mosugelo *et al.*, 2002). Plant diversity was greatly reduced, but the only animal species that suffered much local decline was bushbuck, reduced to a third or less of their former abundance (Skarpe *et al.*, 2004). Savanna woodland away from the river remained little affected (Ben-Shahar, 1993). At Amboseli the vegetation change was drastic, with the extent of fever acacia woodland vastly reduced, except where fenced exclosures kept out elephants (Western, 2007). However, the reduction in browser numbers as a consequence was not drastic, and historical evidence suggested that the development of the fever acacia stands was relatively recent and associated with settlement by pastoral people and their livestock.

As reported earlier, there are reasons to believe that the vegetation impacts of elephants and white rhinos can be beneficial for other large herbivores, through promoting the production of nutritious and accessible plant parts and by generating a mosaic diversity of habitat conditions. However, within local areas the vegetation transformation can reach extremes and can threaten the persistence of many plant species (O'Connor *et al.*, 2007), as well as certain types of animal. For example, the removal of trees is detrimental for the persistence of birds and bats dependent on woodland habitats (Cumming *et al.*, 1997a, 1997b), most notably vultures nesting in tall trees. Issues of spatial scale become central. If the area available is large enough to retain a mosaic of heavily and lightly disturbed areas, the overall biodiversity is likely to be enhanced. However, if the habitat disturbance

becomes too extensive, many species may lose out, particularly certain plants. Hence, the most acute concerns arise with regard to protected areas under 1000 km² in extent (Boundja and Midgley, 2010). Nevertheless, it remains debatable whether even areas as large as Kruger National Park (19,000 km²) are big enough to retain sufficient diversity once its elephant population has reached the habitat capacity, especially if surface water is sufficiently widely available for these animals to distribute their impacts throughout the park extent even in the dry season.

Meanwhile, elephant populations north of the Zambezi River remain threatened by illegal hunting supplying the continuing demand for ivory in the Far East, causing Kenya to oppose any change to existing agreements under CITES (the Convention on International Trade in Endangered Species), which block all trade in ivory. Opposing this is pressure from southern range states to allow sales of their mounting stocks of ivory held in vaults. India also strongly opposes any killing of elephants. Conservation issues concerning elephants are comprehensively summarized in the compendium by Scholes and Mennell (2008).

The white rhino population expansion toward 2000 animals within the 900 km² Hluhluwe-iMfolozi Park, with local densities exceeding five rhinos per square kilometer, raised similar concerns in a more local context (Owen-Smith, 1981, 1988). Culling was initiated by means of live capture and removal to restock other areas, including sales to private land owners. To simulate the role of dispersal in population regulation, the offtake is restricted to zones designated as dispersal sinks. A total of nearly 20,000 white rhinos have been generated from this source population, around half on private land (Emslie, 2008). The auction price fetched per rhino has reached US \$30,000, and legislation allows for males to be shot by hunters, leading some ranchers to breed white rhinos for live sale. However, permits for ownership of hunting trophies have provided a cover for illegal exports of horns from South Africa (Milledge, 2007). Fueled by the extremely high prices paid for rhino horn scrapings used for medicinal purposes in the Far East, rhino poaching has recently increased explosively even in the best protected South African parks.

Black rhinos were formerly widespread through most of Africa, but their numbers have fallen to under 4500 animals, mostly located in South Africa and Namibia. The relatively low density attained by this browser (less than one animal per square kilometer) restricts the population that can be supported in any one area. Hence, a metapopulation management strategy has been introduced, entailing transferring animals from source populations to restock new areas, coupled with movements of breeding males between smaller areas to restrict inbreeding (<http://www.rhino.sadc.org>).

Indian rhinos remain severely threatened by poaching even in the heavily protected sanctuaries established in India and Nepal. Although some animals have been moved into newer parks, total numbers remain under 3000 animals. The Ujung Kulon Reserve retains no more than 50 Javan rhinos, whereas the few animals that had remained in Vietnam have been extirpated, making survival prospects for this species dismal.

The application of dispersal sink or metapopulation management to control wide-ranging elephants seems impractical even for parks as large as Kruger or Tsavo. The

initiatives most supportive for conserving elephants are transfrontier conservation areas (TFCAs) expanding the scope for elephant movements. Kruger Park has been joined with the Limpopo National Park in Mozambique plus private nature reserves to the west to form the Greater Limpopo Transfrontier Park covering 25,000 km², with prospects for further expansion in Mozambique and into Zimbabwe. Even more ambitious is the proposed Kavango-Zambezi (KAZA) TFCA aggregating almost 300,000 km² of parks, wildlife and forest reserves, game management areas, and communal land, extending from Botswana through Caprivi, Zimbabwe, Zambia, and Angola (www.peace-parks.org). Ways need to be found to enable elephants to move through settled areas between the protected areas. Studies in northern Kenya have shown how elephants alter their movements to avoid much contact with people (Graham *et al.*, 2009).

Despite these initiatives, a major conservation issue is the conflicts that arise between rural people and elephants with regard to crop damage, in India as well as in Africa (Sukumar, 2003; Dublin and Hoare, 2004). This tension is increasing where elephant populations are growing and expanding their range into settled areas. It is unclear how an eventual resolution will be achieved, except by fencing elephants out or people in and by allowing the killing of elephants transgressing boundaries.

Final Perspectives

Very large mammals falling within the megaherbivore size range (>1000 kg) were once a major feature of terrestrial faunas in all parts of the world. Megaherbivores still vastly dominate large herbivore biomass in part of Africa. Their grazing, browsing, and damaging impacts can transform uniform forests or grasslands into a mosaic interspersed of woodland, meadow, and savanna parkland. The enhanced habitat heterogeneity and productivity generated by such disturbance of vegetation can be favorable for the coexistence of numerous other mammalian herbivores, although plant diversity may be reduced locally.

Ecological conditions and processes operating within regions lacking megaherbivores differ vastly from those that prevailed in past times, before human hunting intruded. Whether the disappearance of these very large beasts is thankful or regrettable raises value judgments around human land-use objectives. The transforming influences of human settlements and cultivation on landscapes have largely replaced the impacts of megaherbivores. The ultimate resolution of the conflicts with humans where elephants are recovering their numbers and distribution ranges is unclear. From an African perspective, hankering for the restoration of mammoth equivalents in North American ecosystems appears crazy, given the problems that would ensue. Nevertheless, at some time in the future, the accumulated fossil fuels that we have depended on to energize our machines will have become irretrievably depleted. Once this situation develops, we may need to resort back to using these great beasts to perform essential services as environmental engineers and cultivators. Hence, we need to ensure their long-term persistence, at least in Africa.

Glossary

Ancestral Describes a character or character state of the organism being considered that retains the primitive condition for its evolutionary lineage.

Derived Describes a character or character state of the organism being considered that has changed from the ancestral condition for its evolutionary lineage.

Ectothermy Deriving the energy needed to raise body temperature from sources outside the body.

Endothermy Deriving the energy needed to raise body temperature from within the body – i.e., from metabolic heat production.

Heliothermic Regulating body temperature primarily by moving between sun and shade.

Operative temperature A measure of environmental temperature that combines the effects of heat exchange via radiation, convection, with metabolic heat production, and evaporative heat loss.

Paraphyletic A taxonomic grouping of animals that does not meet the cladistic criterion of including the most recent common ancestor and all its descendants.

Sister group The evolutionary lineage most closely related to the one being discussed.

The widespread adoption of phylogenetic systematics (cladistics) as the basis for taxonomic designations has had more impact on our understanding of reptiles than on any other group of terrestrial vertebrates. As our knowledge of ancestral and derived characters of reptiles has grown and been applied over the past decade, our perception of evolutionary relationships of lineages within the Reptilia has changed, and some lineages have even moved in and out of the Reptilia. Our current understanding of the relationships of extant reptiles recognizes three major monophyletic lineages (Pough *et al.*, 2004): Turtles, crocodilians and birds, and lepidosaurs (with tuatara, lizards, and snakes as the extant representatives). Birds are derived from the lineage that includes crocodilians as well as dinosaurs, pterosaurs, and several other groups of extinct reptiles (Chiappe, 2007), but the anatomical and physiological specializations seen at the avian grade (most notably endothermy, insulation, and flight) make birds functionally different from other reptiles. As a result, the precladistic allocation of nonavian reptiles to the field of herpetology and avian reptiles to ornithology is useful, and will be followed here. Nonetheless, the evolutionary origins of the characters of birds provide a useful context for considering the present and past diversity of other reptiles.

Extant Evolutionary Lineages

Reptiles, exclusive of birds, include about 9300 living species. Our understanding of the phylogenetic relationships of the group is in flux. The Reptile Database (<http://www.reptile-database.org/>) is a convenient reference and except where other sources are cited, the author has followed its January 2011 taxonomic divisions. The vast majority of nonavian reptiles (about 9000 species) are lepidosaurs (tuatara, lizards, and snakes). There are approximately 315 living species of turtles and 23 crocodilians (Florida Museum of Natural History <http://www.flmnh.ufl.edu/cnhc/>). Species diversity is greatest in the tropics, but reptiles are not limited to warm

regions – temperate deserts in the Holarctic, Africa, and Australia have rich lizard faunas, and temperate aquatic habitats in North America and Asia are home to many species of turtles. Reptiles occur on every continent except Antarctica, occupy habitats ranging from freshwater swamps to desert salt flats, and exploit ecological zones from subterranean to arboreal.

Turtles (Testudines or Chelonia)

The shell that makes turtles instantly recognizable is formed by bone overlain by horny epidermal scales called scutes. The ribs, vertebrae, and parts of the pectoral girdle are fused to the dorsal shell (carapace), which is connected to the lower shell (plastron) by a bony bridge. The scutes or bone are secondarily reduced in some lineages of turtles, most notably the freshwater soft-shell turtles (Trionychidae) and the marine leatherback turtle (*Dermochelys coriacea*).

The earliest fossils of turtles are from the late Triassic (Joyce and Gauthier, 2004), and two major lineages, Pleurodira and Cryptodira, can be distinguished by the early Jurassic. Pleurodires have the common name side-necked turtles because they bend the neck horizontally when they retract their heads, whereas cryptodires bend their necks vertically. The geographic occurrence of pleurodires is currently restricted to the Southern Hemisphere (although fossil pleurodires are known from the Northern Hemisphere), and all of the approximately 70 species are aquatic. Pleurodires are the only turtles native to Australia and New Guinea and the only aquatic turtles in sub-Saharan Africa.

The approximately 250 species of cryptodires have a worldwide distribution and include specialized marine and terrestrial forms as well as aquatic and semiaquatic species. Tortoises (Testudinidae, about 50 species with a worldwide distribution in temperate and tropical regions) are the most terrestrial turtles. Most tortoises have domed carapaces, and many have forelimbs that are modified for digging. Semiaquatic and aquatic turtles generally have low streamlined

shells and webbed feet. Most of the 125 species of emydid turtles fit this description. Emydids are found primarily in the New World, with one European species, the pond turtle *Emys*. The paraphyletic group “Bataguridae” is the Old World equivalent of the emydids, with about 60 species in Europe and Asia and one genus (*Rhinoclemmys*, 9 species) in the Americas. The sea turtles (Cheloniidae (6 species) and Dermochelyidae (1 species)) are still more specialized for swimming, with forelimbs that are modified as flippers and short necks that cannot be retracted. Sea turtles have a worldwide distribution, primarily in tropical and subtropical regions although the range of the leatherback sea turtle extends well into the North Atlantic and South Pacific.

Crocodylians (Crocodylia)

Crocodylians are part of the archosaur lineage that includes dinosaurs and birds as well as a number of other groups. Most crocodylians are large (at least 1 m in total length) and have bony plates in the skin. These characteristics have contributed to an extensive fossil record that extends back to the middle of the Triassic. Crocodylians reached the height of their diversity in the Mesozoic (Clark, 1997). The history of the group includes terrestrial species, ranging in size from the meter-long *Araripesuchus rattoides* that ate plants and soil-dwelling invertebrates to *Sarcosuchus imperator*, which, at 12 m and tipping the scales at 8000 kg, was as large as tyrannosaur dinosaurs. Metriorhynchids, a group known from the Jurassic and Cretaceous, were highly specialized for marine life with the forelimbs modified as paddles and a lobed tail. They may have been viviparous like some other Mesozoic marine reptiles.

In contrast to their rich Mesozoic history, crocodylians are the smallest group of extant reptiles, with only 23 species. Crocodylians are primarily inhabitants of tropical and subtropical regions, but the American and Chinese alligators (*Alligator mississippiensis* and *A. sinensis*) are found in temperate areas. All living crocodylians are aquatic; they swim with lateral undulations of the tail, which is somewhat flattened laterally. The nostrils of crocodylians are at the tip of the snout and are slightly elevated, as are the eyes. Alone among non-avian reptiles, crocodylians have developed a secondary palate that separates the passageway for air from the oral cavity. This combination of characters allows crocodylians to float with only the eyes and nostrils exposed.

Three lineages of extant crocodylians are recognized. The Alligatoridae includes eight species of freshwater crocodylians. All except the Chinese alligator occur in the New World. *Paleosuchus* (dwarf caimans) are among the smallest crocodylians at 1.7 m total length, and *Melanosuchus niger* (6 m) is one of the largest. Alligatorids have relatively broad snouts and the teeth of the lower jaw fit into pits in the upper jaw and cannot be seen when the mouth is closed. Crocodylids have narrower snouts than alligators, and the fourth tooth of the lower jaw of a crocodile is visible when the mouth is closed. The 14 species of crocodiles have a worldwide distribution, primarily in tropical and subtropical regions. Several species of crocodiles, especially the American crocodile (*Crocodylus acutus*) and the saltwater crocodile (*C. porosus*), regularly make

long sea journeys, and the saltwater crocodile has colonized islands 1000 km from the nearest mainland. The saltwater crocodile is the largest species, growing to a length of more than 7 m. The African dwarf crocodile, *Osteolaemus tetraspis* (2 m), is the smallest member of the family. The Gavialidae includes just one species, the gharial (*Gavialis gangeticus*), found in northern India and Nepal. It is a specialized fish eater with a long, extremely narrow snout. A similar but less specialized long-snouted fish eater, the false gharial *Tomistoma schlegelii* from the Indonesian Archipelago, is placed in the Crocodylidae by some authorities and in the Gavialidae by others.

Lepidosauria (Lepidosauria)

More than 95% of living reptiles are lepidosaurs, and unlike turtles and crocodylians, this lineage displays enormous diversity in body form and ecology. Lepidosauria are covered by scales (the name means “scaly reptile”) and they shed the skin at regular intervals. They have a transverse cloacal slit (rather than the longitudinal slit seen in crocodylians and turtles), and many species exhibit caudal autotomy that is facilitated by fracture planes within the vertebrae of the tail. Lepidosauria include two lineages of extant forms, the Rhynchocephalia (the tuatara of New Zealand) and the Squamata (snakes and lizards) (Evans and Jones, 2010). Like their sister group, the Archosauria, lepidosaurs are diapsid (i.e., primitively they have two fenestrae defined by bony arches on the sides of the skull). Modifications of the diapsid condition help to define subgroups within lepidosaurs and contribute to functional differences in prey handling.

Rhynchocephalia

The Rhynchocephalia, as it is currently understood (Gauthier *et al.*, 1988), includes several extinct forms dating back to the Triassic and a single extant lineage, the Sphenodontidae, represented by a single, genetically variable species of tuatara (*Sphenodon punctatus*) that is found only on islands off the coast of New Zealand (Hay *et al.*, 2010).

Tuatara are lizardlike in body form and reach a total length of about 50 cm. (Tuatara is a Maori word meaning “spines on the back” and does not add an s to form the plural.) Unlike their sister group, the Squamata, tuatara retain the fully diapsid skull condition, with a lateral opening that is bounded dorsally by the postorbital and supratemporal bones and ventrally by the supratemporal and jugal. These bony connections impart rigidity to the skull that allows tuatara to deliver a forceful bite. The single row of teeth on the lower jaw fits between two rows of teeth in the upper jaw – an outer row on the maxilla and an inner row on the palatines – and prey is chewed to a pulp before it is swallowed. Tuatara lack the paired hemipenes (intromittent organs) that characterize squamates.

Squamata

A large number of anatomical features characterize squamates. Prominent characteristics are reductions in the bony connections forming the arches in the skull, allowing a degree of kinesis unknown in other nonavian reptiles, and the presence

in male squamates of paired hemipenes that develop as outgrowths of the posterior wall of the cloaca and are housed in the base of the tail. The hemipenes, which are everted in use, are held in the female's cloaca by spines, and sperm passes along a lateral groove.

Reduction or loss of limbs, usually accompanied by elongation of the trunk and tail, is a recurrent theme among squamates that reaches its zenith in snakes. Phylogenetically, snakes are included within lizards, but the abundance and diversity of snakes combined with their morphological, ecological, and behavioral specializations make it helpful to discuss lizards and snakes separately.

Lizards

Fossils of lizards are known from the middle Jurassic, and the major lineages were distinct by the end of the Mesozoic. Lizards are found on every continent except Antarctica and are well represented on oceanic islands because large species, such as iguanas, can survive long journeys from the mainland on floating vegetation, and small species (most notably skinks and geckos) often travel as stowaways with humans.

The more than 3000 species of extant lizards can be assigned to 22 families (Pough *et al.*, 2004), three of which are very large: Scincidae (more than 1000 species), Iguanidae (more than 900 species), and Gekkonidae (870 species). Skinks and geckos have worldwide distributions, whereas only three genera of iguanids are found outside the New World (*Brachylophus* on Fiji, and *Oplurus* and *Chalarodon* on Madagascar).

Most species of iguanids are diurnal, visually oriented lizards whose activities and social behaviors can easily be observed, and they occur in areas accessible to biologists. As a result, iguanids figure prominently in ecological and behavioral studies of lizards. The family as it has traditionally been defined included several genera of large herbivorous lizards (the Iguaninae) and a variety of smaller, primarily insectivorous species that were placed in other subfamilies (Etheridge and de Queiroz, 1988). A review of anatomical characters elevated the subfamilies of Iguanidae to family status, leaving only the large herbivores in the Iguanidae (Frost and Etheridge, 1989). This reclassification had a broad impact on the biological literature, because the newly elevated families include species that have formed the basis for much of the research on lizards. More recently, an analysis based on molecular characters has supported the traditional interpretation of Iguanidae (Macey *et al.*, 1997), and that classification is used here.

Snakes

Phylogenetically snakes are included within lizards, and the most primitive snakes, aniliids and uropeltids, lack many of the derived characters that are responsible for the distinctive ecology and behavior of advanced snakes. Even primitive snakes have greatly increased the number of preloacal vertebrae, however, and have lost the bony connection between the postorbital and supratemporal bones, freeing the supratemporal to rotate on its flat articulation with the parietal. This anatomical change allows the supratemporal and quadrate bones to act as part of the lower jaw, and these bones show

varying patterns of elongation in advanced lineages of snakes. The brain of snakes is enclosed in a rigid box formed by ventral extension of the frontal and parietal bones and their articulation with the sphenoid bone.

Snakes are clearly derived lizards, but the sister group of snakes and the conditions that led to their evolution are still controversial topics. Snakes focus images on the retina by moving the lens, whereas lizards focus images by changing the shape of the lens. This difference and differences in the photosensitive cells in the retinas of lizards and snakes have long been interpreted as indicating that snakes are derived from a subterranean lineage of lizards with degenerate eyes. Other hypotheses of the origins of snakes are plausible, although they do not specifically account for differences in the eye. For example, legs are not particularly useful to small squamates that live in dense vegetation such as clumps of grass, and this is the habitat occupied by many legless lizards. This epigeal adaptive zone might provide an intermediate stage in the evolution of snakes. Alternatively, aquatic habits could have been an intermediate stage in the evolution of snakes. *Pachyrachis problematicus*, a recently described elongate aquatic lepidosaur from Cretaceous marine deposits, was more than a meter long and had more than 100 presacral vertebrae and a skull that shows many of the derived features of snakes, including envelopment of the brain by bone (Caldwell and Lee, 1997). Two recent molecular studies, however, support the hypothesis of a terrestrial origin of snakes (Townsend *et al.*, 2004; Vidal and Hedges, 2004).

Snakes were apparently widespread by the late Cretaceous; fossils of that age are known from India, Africa, and South America. Most fossils consist of isolated vertebrae, but vertebral characters play a minor role in classification of living snakes and it is difficult to associate these fossils with extant lineages. Snakes radiated extensively in the Cenozoic, and about a dozen families are usually recognized, containing more than 2500 species. Primitive snakes, including boas and pythons, can be compared to more advanced forms, the Caenophidia, which include elapids (cobras, coral snakes, sea snakes, and their relatives), viperids (pit vipers and true vipers), and the Colubroidea, a category that contains more than two-thirds of the total number of extant species of snakes (Zaher *et al.*, 2009).

Ancestral and Derived Characters

The functional ecology of reptiles is shaped by a combination of ancestral and derived characters, and an appreciation of these features and the ways in which they interact is central to understanding how reptiles function as organisms. Important derived characters include reproduction via a shelled egg (with the secondary development of viviparity in many lineages), excretion of nitrogenous wastes as urate salts, and a dry skin that is relatively impermeable to the passage of water. Retained ancestral characters include ectothermal thermoregulation (with the accompanying low metabolic rate and the absence of an insulating layer of hair or feathers) and an anatomically three-chambered heart (except in crocodilians) that permits intracardiac blood shunting.

Sex Determination

Both genetic sex determination (GSD) and environmental (temperature-dependent) sex determination (TSD) occur in reptiles (reviewed by Sarre *et al.*, 2004). Heteromorphic sex chromosomes have been described in some species of turtles (male heterogamety: XY or XXY), snakes (female heterogamety: ZW, ZZW, or ZWW) and lizards (both male and female heterogamety), but other species in those groups are homogametic. Crocodilians and the tuatara lack heteromorphic sex chromosomes (Huchzermeyer, 2003; Norris *et al.*, 2004).

GSD occurs in most species of reptiles with heteromorphic sex chromosomes as well as in some species with homomorphic sex chromosomes. TSD is characteristic of the tuatara, all crocodilians, and many species of turtles and lizards, including some species with heteromorphic sex chromosomes. Sarre *et al.* (2004) proposed that GSD and TSD are the ends of a continuum. This view is supported by the observation that in some species, temperature can override GSD to produce individuals that are phenotypically male and genotypically female or the reverse (Quinn *et al.*, 2007).

Temperature acts on gonadal development during a critical period in embryogenesis. For turtles, the tuatara, and especially crocodilians, the critical period occurs after the eggs have been deposited in the nest, but for lizards the critical period occurs while the eggs are still within the oviducts of the female (Shine *et al.*, 2007). Pieau and Dorizzi (2004) argued that TSD is produced by the effect of temperature on the gonads alone, and that no extragonadal tissues are involved.

The ecological and evolutionary significance of TSD have been debated since the phenomenon was described (Shine, 1999). The Charnov–Bull model proposes that TSD maximizes the fitness of parents by adjusting the sex of the offspring to the nest temperature, and that relationship has been demonstrated experimentally for an Australian agamid lizard (Warner and Shine, 1998).

Temperature and Water Relations

With the exception of a few very large species, nonavian reptiles are ectotherms. That is, they obtain the energy they need to raise body temperatures to activity levels from external sources, either directly from the sun or via contact with surfaces that have been heated by the sun. Reptiles employ a mixture of behavioral and physiological mechanisms of thermoregulation: They move between sun and shade, orient the body to maximize or minimize interception of solar radiation, and concentrate or disperse melanin to change reflectivity. These mechanisms are supplemented by intracardiac shunting of blood and adjustments of the peripheral circulation to accelerate or retard exchange of heat with the environment. In contrast, birds and mammals are endotherms, changing the insulation provided by hair or feathers and adjusting metabolic rate to match rates of heat production and heat loss.

Ectothermy imposes some limits on reptiles. When heat sources are not available – at night for example, in water, or beneath the closed canopy of a tropical forest – reptiles must either accommodate their temperature requirements to the ambient temperature or cease activity. In the absence of

environmental constraints, however, ectothermal thermoregulation can produce body temperatures that are as high and as stable as those of birds or mammals. Lizards and snakes, especially species that live in open habitats, generally control their body temperatures within activity temperature ranges of 2–3 °C. Terrestrial turtles, too, control their body temperatures by moving between sun and shade during periods of activity. The large body sizes of some turtles and crocodilians stabilize their body temperatures. Leatherback sea turtles, which weigh up to 1000 kg, are found off the coasts of New England and Nova Scotia in the summer in water temperatures as low as 8 °C. A countercurrent exchange mechanism in the flippers conserves the heat produced by muscular activity as the turtles swim, and body temperatures can exceed water temperature by more than 15 °C (James and Mrosovsky, 2004).

The dry skin of reptiles is an essential component of their ectothermal thermoregulation. In contrast, the high rate of evaporation from the moist skins of extant amphibians limits their capacity to maintain body temperatures above ambient levels as well as their ability to be active during the day when evaporative stress is high. Reptilian water balance is additionally facilitated by enzymatic pathways that convert nitrogenous waste to uric acid, which is excreted as a complex mixture of urate salts. The shelled eggs of reptiles absorb water from the substrate during development, and the availability of water in the nest environment influences the body size and, probably, the viability of newly hatched reptiles.

Metabolism and Energetics

Because ectotherms do not depend on metabolic heat production for thermoregulation, their resting metabolic rates are low – one-seventh to one-tenth those of endotherms of the same body size. The influence of low resting metabolic rates can be seen in the energy use, body size, and the exercise physiology and foraging behavior of reptiles.

Energy Requirements and Conversion Efficiency

The daily energy budget for a lizard is only 3% of the energy requirement for a mammal of the same body size (Bennett and Nagy, 1977). Low energy use by the lizard results partly from its low resting metabolic rate during the day when it is active and partly from a reduction in body temperature (with a consequent further reduction in metabolic rate) at night when it is inactive. In contrast, a mammal maintains a higher metabolic rate during the day and may increase its metabolic rate above resting levels at night to counteract the effect of falling ambient temperature.

Low metabolic rates translate to low energy requirements for reptiles. As a result, reptiles can cope with environments in which food is limited, either episodically or permanently. Areas of low primary production, such as deserts, and even regions where there is no primary production, such as desert salt flats and mobile sand dunes, are home to a variety of lizards.

Efficient conversion of food to biomass is a second consequence of the low metabolic rates of reptiles. Endotherms use most of the energy they ingest to stay warm and be active – 19 species of birds and mammals have an average net

conversion efficiency of 1.4% (range 0.5–3%), whereas nine species of reptiles have an average net conversion efficiency of 46.6% (range 18–86%) (data from Pough, 1980).

Body Size

Mass-specific metabolic rates ($W\ g^{-1}$) are related to body mass by an exponent that approximates -0.25 , although statistically significant variation from that value is associated with both phylogeny and ecology (Hayssen and Lacey, 1985; Andrews and Pough, 1985). The consequence of that negative allometry is a mass-specific energy requirement that increases steeply as body size decreases (Figure 1).

The low metabolic rate of reptiles makes extremely small body size energetically feasible, and lizards, in particular, include very small species. The modal body mass of lizards falls in the range 1–10 g, and nearly 20% of lizards have adult body masses less than 1 g. In contrast, there are no mammals with adult body masses less than 1 g, and fewer than 5% of mammals have body masses below 10 g (see Pough *et al.*, 2009, p. 386). More than half the living species of lizards occupy a zone of body sizes in which there are practically no mammals, and the smallest lizards have their major competitive and predatory interactions with invertebrates. In contrast to lizards, snakes are relatively large reptiles – nearly 80% of snakes are larger than 20 g. Thus, snakes and lizards illustrate two different ways to succeed as a squamate in a world that is largely dominated by endotherms: Small body size is a morphological specialization of lizards, just as elongation and skull kinesis are morphological specializations of snakes.

Exercise Physiology and Behavior

The low resting metabolic rates of reptiles limit their aerobic metabolic capacity – i.e., the maximum rates of oxygen

consumption they can achieve during strenuous activity. Both reptiles and mammals increase resting rates of oxygen consumption about 10-fold when they run at maximum speed, so the differential in metabolic rates of ectotherms and endotherms persists during activity. Most reptiles have limited aerobic metabolic capacity, and they derive most of the ATP used during high levels of activity from anaerobic pathways.

Glycogen, the metabolic substrate for anaerobic metabolism, is stored in the muscle cells and a brief period of activity can exhaust the muscles' glycogen supply. As a result, anaerobic metabolism is an effective way to support bouts of intense muscular activity, but it is not suitable for sustained behaviors such as long-distance locomotion. The activity patterns of many reptiles are built on this relationship – they employ sit-and-wait modes of foraging, they escape predators by fleeing to a nearby shelter, and their social behaviors do not include sustained high levels of activity.

Active Reptiles and the Evolution of Endothermy

In an ecological context, the generalization that reptiles are ectotherms with low metabolic rates and low levels of activity applies to extant species, although some modifications of that characterization will be addressed in subsequent sections. In an evolutionary context, however, the generalization is patently false because birds are reptiles and they are endotherms with high metabolic rates. Clearly the reptilian lineage has a capacity for endothermy that is barely expressed in nonavian reptiles. An examination of the evolution of endothermy explains that dichotomy and emphasizes how tightly anatomical and physiological characteristics are linked to thermal ecology.

Ectothermy is the ancestral condition for vertebrates, and the derived condition of whole-body endothermy has evolved at least twice, in mammals and in birds. In a broader view, regional endothermy has evolved independently in sharks, tunas, and billfishes, and whole-body endothermy may have been characteristic of pterosaurs (flying archosaurian reptiles of the Mesozoic) and some lineages of dinosaurs.

Ectotherms and endotherms have very different relationships to their physical environments: Ectotherms rely primarily on behavioral thermoregulation to raise their body temperatures because they have low metabolic rates, and the absence of insulation facilitates uptake of heat from the environment. In contrast, endotherms use internal heat production from high metabolic rates to regulate body temperature, and they require insulation to retain metabolic heat in their bodies.

The evolutionary transition from ectothermy to endothermy is complicated by a Catch-22 – adding insulation to an ectotherm impairs its behavioral thermoregulation, but in the absence of insulation, any heat produced by increasing its resting metabolic rate is lost to the environment. The solution to this paradox lies in finding a basis for the evolution of insulation or the evolution of an increased metabolic rate that does not depend on the pre-existing occurrence of the other character.

Mammals are the sister group of reptiles (including birds), and the common ancestor of mammals and reptiles was ectothermal. Thus, the evolution of endothermy in the mammalian lineage may provide a model for the evolution of endothermy among reptiles. Anatomical changes seen in the

Figure 1 The mass-specific energy requirements of animals increase at small body sizes. The metabolic rates of reptiles are one-seventh to one-tenth those of birds or mammals of the same body size, and the smallest reptiles have adult body masses less than 1 g, whereas very few birds and mammals are smaller than 10 g as adults. Modified from Pough FH (1980) The advantages of ectothermy for tetrapods. *American Naturalist* 115: 92–112, with permission from University of Chicago Press.

fossil record of predatory synapsids, the sister group of mammals, strongly support the hypothesis that the initial step in the evolution of mammalian endothermy was the selection of increased locomotor capacity. These changes include the evolution of a cursorial body form, changes in the rib cage that suggest the presence of a diaphragm, and increased surface area in the nasal passages to warm and humidify large volumes of air. Increasing levels of locomotor activity require an increase in metabolic rate, and internal heat production would create a selective value for insulation (see Pough *et al.*, 2009, Chapters 11 and 18, for details and references).

Some features of the fossil record of birds suggest that a similar scenario can be applied to the evolution of avian endothermy, but others appear to contradict that interpretation. Like the predatory synapsids, the small maniraptoran dinosaurs that form the sister group of birds appear to have been fleet-footed predators that pursued their prey. This interpretation suggests that these dinosaurs may have evolved the metabolic capacity for endothermy just as synapsids did, and the impressions of feathers in fossil dinosaurs supports this interpretation. However, two lines of evidence cast doubt on the hypothesis that the dinosaurian precursors of birds had high metabolic rates. Examination of an excellently preserved specimen of the small dinosaur *Sinosauropteryx* suggests that it had simple septate lungs that were ventilated by a piston-like movement of the liver like those of living crocodilians. Lungs of this sort would not support high rates of oxygen consumption. This interpretation is supported by CAT scans of the nasal passages of dinosaurs that reveal no trace of modifications of the nasal passages to warm and humidify large volumes of air (Ruben *et al.*, 1996).

This evolutionary perspective emphasizes intricate interconnections among the anatomical and physiological characters of extant reptiles and their ecology and behavior, as well as the evolutionary capacity for breaking those links. An examination of living reptiles reveals additional connections among anatomy, physiology, ecology, and behavior.

Characteristics of Groups

Evolution proceeds in a mosaic fashion; all descendant lineages inherit ancestral characteristics, and each lineage develops a set of derived characters that interact with ancestral characters and with each other to shape the way animals live. The following sections focus on combinations of ancestral and derived characters found in specific groups of reptiles that are important in shaping their ecology and behavior. TSD is widespread among turtles, for example, and crocodilians show extensive parental care. To avoid repetition, examples from other lineages are included when a topic is discussed. Additional details, examples, and references can be found in Pough *et al.* (2009); Pough *et al.* (2004), and the sources cited.

Turtles

The Nest Environment and the Size and Sex of Hatchlings

All turtles lay eggs in holes which they excavate with their hind legs. Physical conditions within the nest determine both the size and the sex of hatchlings of many species of turtles

(Packard and Packard, 2000). In general, embryos in nests constructed in moist substrates metabolize most of their yolk before they hatch and grow larger than embryos in drier nests. Hatchlings of snapping turtles (*Chelydra serpentina*) from moist nests run and swim faster than the smaller hatchlings that emerge from dry nests. This difference in locomotor performance, which persists for at least a year after hatching, might result in higher first-year survival of hatchlings from moist nests.

TSD is widespread among both pleurodires and cryptodires. For most species of turtles, low temperatures during incubation produce males (Pattern Ia), but in a few species males are produced at high temperatures (Pattern Ib), and some species show a biphasic response in which females develop at both low and high temperatures and males are produced at intermediate temperatures (Pattern II). Environmental sex determination can produce both male and female hatchlings from the same nest, because the shift between sexes typically occurs within a range of only 1–2 °C. Thus, eggs from the top of a nest can develop into females while eggs deeper in the same nest produce males, or clutches laid early in the season when nest sites are exposed to the sun can produce females, whereas clutches laid in the same sites later in the summer produce males because the nests are now shaded by vegetation.

Gigantism

Giant tortoises are among the most spectacular reptiles. The largest species of living tortoises are found on the Galápagos and Aldabra Islands and reach carapace lengths of more than a meter and body weights exceeding 100 kg, but large tortoises are not limited to islands. Extant members of the genus *Geochelone* have a pantropical distribution, with mainland representatives in Africa, India, Asia, and South America as well as additional island species on Madagascar, Sri Lanka, and Indonesia (Ernst and Barbour, 1989; Pritchard, 1996). The largest living mainland species, the African spur-thighed tortoise *G. sulcata*, reaches a carapace length of 76 cm, and fossil tortoises with carapace lengths from 60 cm to 1.5 m are known from Pleistocene deposits on all of the continents except Australia and Antarctica. Giant tortoises were present in North America when humans arrived, and a subfossil carapace from Florida contains a spear point and is charred as if it had been placed upside down and cooked on fire.

Crocodilians

Reproduction and Parental Care

All crocodilians are oviparous, laying eggs either in nests that the female excavates in the ground or in mounds of vegetation that the female builds. Crocodilians in some areas are reported to lay eggs on floating mats of vegetation. Parental care is probably universal among extant crocodilians, although the reproductive behavior of some species is unknown, and parental care appears to have been reduced in populations that have been hunted extensively (Lang, 1989). Females are the primary caregivers, but males often participate. A female crocodilian remains near her nest while the eggs are incubating. As the young approach hatching, they start to vocalize within the eggshells, and these vocalizations signal the female

to begin opening the nest. The male may participate in opening the nest, and both parents pick up hatchlings in their mouths and transport them to water. Adult crocodilians show remarkable dexterity in this process, sometimes picking up an intact egg and cracking the shell to release the hatchling.

Parental care is virtually unknown among turtles, but about 100 species of squamates exhibit some degree of parental care (Shine, 1985; Gans, 1996). These behaviors range from defense of the nest site to brooding the eggs. In an exception to the generalization that reptiles are ectotherms, females of some species of python gather their eggs into a clump encircled by coils of the body and use muscular contractions to keep the temperature of the eggs close to 32 °C. The frequency of contractions, and thus the python's rates of oxygen consumption and heat production, increases as ambient temperature falls. A female Indian python (*Python molurus*) can maintain her egg mass at 31–32 °C at ambient temperatures between 23 and 32 °C, and functions as an endotherm during this period.

Lepidosaurs

Tuatara

Tuatara have a number of unusual ecological and physiological characteristics. They are crepuscular and forage on cool, foggy nights, with body temperatures as low as 6 °C. During the day, tuatara bask in the sun and raise their body temperatures to 28 °C. Tuatara feed on invertebrates and nestling shearwaters. The prey is crushed as the lower jaw closes with an initial vertical movement and is then sheared by the interdigitating rows of triangular teeth as the lower jaw slides forward.

Tuatara, unlike other lepidosaurs, lack hemipenes. Sperm is transferred by apposition of the cloacas of the male and female. In late spring, female tuatara excavate shallow depressions in which they deposit 6–15 eggs. Embryonic development requires 12–15 months (Saint Girons, 1985).

Tuatara are the sister group of squamates, and their anatomy shows characters that are probably ancestral for squamates, including the connection between the jugal and supratemporal bone forming the lower border of the lateral arch of the skull. Some authors have used the phylogenetic position and primitive anatomical characters of tuatara as a basis to suggest that their ecology and physiology also reveal ancestral conditions for squamates, but this is probably not the case. New Zealand is a cold place, and the native geckos and skinks are active at body temperatures well below those of geckos and skinks in warmer parts of the world. It seems most likely that the low activity temperatures of tuatara and the slow development of their eggs are derived characters that reflect current ecological conditions.

Squamata

Lizards have proven to be ideal study-animals. Many lizards are diurnal and have limited home ranges, so their activities can readily be observed. As a result of their ease of study, species of *Anolis*, *Sceloporus*, *Pogona*, *Urosaurus*, and *Uta* have played seminal roles in the fields of animal behavior, ecology, and evolutionary morphology and physiology (Greer, 1989; Vitt and Pianka, 1994; Wainwright and Reilly, 1994; Pianka

and Vitt, 2003). Most snakes, in contrast, are secretive in their behavior and direct observation is much more difficult. Nonetheless, the combination of perseverance with radio-telemetry has produced several important field studies (Shine, 1991; Seigel and Collins, 1993; Greene, 1997).

Lizards

Classifying species of lizards in terms of the foraging modes they employ provides a framework that organizes diverse aspects of their biology into a series of useful generalizations (Table 1). Like other mobile animals, lizards display a spectrum of foraging behaviors which extends from species that perch motionless on lookouts and make short dashes to capture prey to species that are in nearly continuous motion as they forage, searching for hidden prey under leaf litter and in holes and cavities. Species at the inactive end of this spectrum are called sit-and-wait predators, those in the middle are cruising foragers, and the species that move continuously are called active foragers.

Sit-and-wait lizards rely on vision to detect moving prey and may be selective in deciding on which prey to attack. Widely foraging lizards examine places where prey may be hiding; olfaction is an important sensory mode for these species, and they usually take any prey items they encounter.

Sit-and-wait lizards are usually cryptic and are most likely to be detected by widely foraging predators, whereas widely foraging lizards are conspicuous because of their movement and are consequently vulnerable to sit-and-wait predators. Thus, there may be an alternation of predatory modes at successive levels in a food chain – widely foraging predators find sedentary prey and are eaten by sit-and-wait predators. In the American Southwest, for example, whiptail lizards (*Cnemidophorus*) forage widely and locate sedentary insects such as termites. Leopard lizards (*Gambelia wislizenii*) wait motionless beneath bushes and capture whiptail lizards when they come within range. In turn, leopard lizards are captured by coach-whip snakes (*Masticophis flagellum*), which move from bush to bush in search of prey.

The quick dash that a sit-and-wait lizard makes to capture prey requires high sprint speed, whereas the continuous movement of a widely foraging predator requires endurance. These characteristics are reflected in the physiology of lizards – sit-and-wait lizards can sprint rapidly, but they rely primarily on anaerobic metabolism and have limited endurance. Widely foraging lizards cannot sprint so fast, but they have relatively larger hearts and higher hematocrits than sit-and-wait species, so they have greater aerobic metabolic capacities and greater endurance.

The colors of sit-and-wait lizards often match the backgrounds on which they rest, and their patterns obscure the outlines of the body, making them cryptic when they are motionless. Widely foraging lizards move across a variety of backgrounds and do not necessarily match any particular one. They are often solid-colored or striped, and these patterns may confuse predators when a lizard is moving. Sit-and-wait lizards are exhausted by brief periods of rapid locomotion, and when they are attacked, they sprint to shelter. Widely foraging lizards often run from bush to bush, changing direction when they are out of sight and travelling a long distance before they stop. The generally long tails of widely foraging

Table 1 Ecological and behavioral characteristics associated with the foraging modes of lizards^a

Character	Foraging mode		
	Sit-and-wait	Cruising forager	Widely foraging
<i>Foraging behavior</i>			
Movements/hour	Few	Intermediate	Many
Distance travelled/hour	Small	Intermediate	Large
Primary sensory mode	Vision	Vision and olfaction	Olfaction
Exploratory behavior	Low	Intermediate	High
<i>Predators and prey</i>			
Types of prey	Mobile, large	Intermediate	Sedentary, often small
Types of predators	Widely foraging	?	Sit-and-wait and widely foraging
Risk of predation	Low	?	High
Mode of escape	Cryptic, flee a short distance to shelter when attacked	?	Conspicuous, may flee a long distance when attacked
<i>Physiological characteristics</i>			
Sprint speed	High	?	Low
Endurance	Low	?	High
Aerobic metabolic capacity	Low	?	High
Anaerobic metabolic capacity	High	?	Low
Heart mass	Low	?	High
Hematocrit	Low	?	High
<i>Energetics</i>			
Daily energy expenditure	Low	?	High
Daily energy intake	Low	?	High
<i>Social behavior</i>			
Social system	Territorial	?	Not territorial
Home range	Small	Intermediate	Large
<i>Body form</i>			
Trunk	Stocky	Intermediate	Slim, elongate
Tail	Often short	?	Often long
Color and pattern	Often blotched, may match background, rarely colorful	?	Often solid or striped, sometimes colorful
<i>Reproduction</i>			
Mass of clutch relative to mass of female	High	?	Low
Viviparity	Often	Sometimes	Rare

^aForaging modes are presented as a continuum from sit-and-wait to widely foraging species. In most cases, data are available only for species at the extremes of the spectrum. Source: Modified from Pough FH, Andrews RM, Cadle JE, Crump ML, Savitzky AH, and Wells KD (2004) *Herpetology*, 3rd edn. Saddle River, NJ: Prentice Hall.

lizards may facilitate caudal autotomy as a last-ditch means of escape.

Sit-and-wait lizards can survey their surroundings from their perches whereas widely foraging lizards can see little beyond their immediate horizon. Sit-and-wait species have small home ranges and are often territorial, whereas widely foraging species have larger home ranges and are rarely territorial. The bulk of eggs within the oviducts are probably a handicap for a widely foraging lizard, and widely foraging species have smaller ratios of clutch mass to maternal mass than the sit-and-wait species. Viviparity is more common among sit-and-wait lizards than among widely foraging species.

These generalizations organize a large number of empirical observations into a coherent whole, but assigning evolutionary cause-and-effect interpretations to the correlations may confound phylogeny with ecology. Most of the sit-and-wait species that have been studied are in the iguanian

lineage, whereas the widely foraging lizards are scincomorphs. Thus, the effects of phylogeny (iguanian vs. scincomorph) cannot be separated from those of ecology (sit-and-wait vs. widely foraging). However, a study of several closely related species of lacertid lizards identified sit-and-wait and widely foraging species, and detected many of the same behavioral and physiological correlations that are found in the broader comparison (Huey *et al.*, 1984).

Because many species of lizards use behavioral mechanisms to regulate their body temperatures within narrow limits while they are active, the thermal environment plays a central role in defining the niche of a species. The thermoregulatory characteristics of habitats can be defined as high cost or low cost, depending on the behavioral and ecological trade-offs a lizard must make to maintain a body temperature that is different from ambient temperatures. Lizards that live in habitats in which basking sites, perches, and escape sites are abundant and

close to each other have low ecological and behavioral costs of thermoregulation and are likely to maintain body temperatures within a narrow range during activity. In contrast, lizards that live in habitats where basking sites are scarce or ephemeral, such as the understory of a tropical forest, have high costs of thermoregulation. These lizards often have body-temperatures indistinguishable from ambient temperature.

The costs of thermoregulation in a particular habitat are not the same for all lizards because body size profoundly affects the thermoregulatory options available to a lizard. An example is provided by three species of *Ameiva* that live in microsympatry on the Osa Peninsula of Costa Rica. The three species partition the structural habitat on the basis of the radiant environment. Adults of the smallest species (*A. quadrilineata*) weigh about 10 g and forage in short vegetation in full sun, whereas the middle species (*A. festiva*) weighs about 32 g and forages in areas where taller vegetation provides broken shade. The largest species (*A. leptophrys*) weighs 83 g and forages in deep shade beneath the forest canopy.

Ameiva are widely foraging lizards, and the three species display the same alternation of thermoregulatory and foraging behaviors: A lizard basks in the sun until its body temperature reaches 39 or 40 °C, and then forages until its body temperature cools to 35 °C when it ceases foraging and basks again. The rate of cooling is inversely proportional to body size, and relative rates of cooling appear to explain the differences in foraging sites of the three species. *Ameiva quadrilineata* cools from 40 to 35 °C in 4 min, compared to 7 min for *A. festiva* and 12 min for *A. leptophrys*. The slow cooling of *A. leptophrys* allows it to move deep under the canopy before it has to return to the forest edge to bask, whereas the smaller species cool too rapidly to move far from basking sites.

A different physical relationship apparently prevents the two larger species from foraging in the sun-drenched habitat occupied by *A. quadrilineata*. The equilibrium temperature reached by an object in the sun is sensitive to its size. The equilibrium temperatures of small objects are strongly affected by convective heat exchange, whereas the equilibrium temperatures of larger objects are closely tied to the radiant environment. As a result of this physical relationship, under the conditions on the Osa Peninsula, an *A. quadrilineata* in full sun reaches equilibrium at 39 °C, which is within its activity temperature range. In contrast, if an *A. festiva* or *A. leptophrys* remained in the sun, its body temperature would rise to a lethally high level.

Thus, the effectiveness with which each species can use a specific thermal environment appears to contribute to habitat partitioning by these species – the forest floor is a high-cost environment for the small and medium species and only the largest species can forage effectively in that habitat. Conversely, the absence of shade creates high costs of thermoregulation for the large and medium species in the open habitat, and only the smallest species can exploit this area.

Snakes

Elongation of the body is the immediate distinctive feature of snakes, and specializations associated with feeding form the core of their diversity. The body form of snakes results primarily from an increase in the number of vertebrae in the neck and trunk, and the longest species have more than 400

precaudal vertebrae. Even generalized snakes – rat snakes (*Elaphe*), gopher snakes (*Pituophis*), Australian whipsnakes (*Demansia*), and blacksnakes (*Pseudechis*) – have head-plus-trunk lengths which are 10–14 times the maximum trunk circumference. In contrast, elongate lizards (*Cnemidophorus*, *Egernia*, *Lacerta*, and *Eumeces*) have length/circumference ratios of 2.0–2.5.

In a functional sense, repackaging the mass of a lizard into a long, thin body form means that a snake must feed a large body through a small mouth. Lizards and snakes almost always swallow their prey whole; many lizards manipulate prey items in their mouths until they have been softened by repeated bites, whereas nearly all snakes swallow prey without any oral processing. Most legless lizards eat large numbers of small prey items; they retain the connection between the postorbital and supratemporal bones on the side of the skull, and this structure gives the skull sufficient rigidity to crush the exoskeletons of insects. In contrast, snakes have lost the postorbital–supratemporal connection and have replaced the body symphysis at the front of the lower jaw with a flexible ligament. These changes, which increase skull kinesis and allow the lower jaws to move independently, also reduce the ability of snakes to exert pressure on food in the mouth. A few snakes have secondarily evolved modifications of the skull and jaws that allow them to eat hard-bodied prey, but most snakes feed on soft prey.

Lizards normally consume several small prey items (or a large item ingested in several pieces) on a daily basis, whereas most snakes can swallow prey items with diameters larger than the snake's head, and eat less frequently.

The prey of snakes is large relative to the predator, and many snakes have specializations (such as constriction or venom) that allow them to immobilize prey before it can injure the snake. Prey size must be evaluated relative to the size of a snake in two respects – mass and diameter. That is, a prey item can be light or heavy compared to the snake that eats it and it can also be slim or bulky. The first comparison can be called relative mass and the second relative girth.

These two variables create four categories of prey (Greene, 1997):

1. Type I prey have both small mass and small girth ratios. Insects are Type I prey, and this is the prey type that is characteristic of most lizards and probably of the earliest snakes.
2. Type II prey are elongate and combine a large mass ratio with a small girth ratio. Earthworms, caecilians (elongate, burrowing amphibians), eels, and other snakes are examples of Type II prey. These food items require specializations to immobilize the prey (constriction or venom), but do not require large gapes. Most primitive snakes (e.g., the pipe snakes, *Cylindrophis* and *Anilius*) are limited to Type II prey.
3. Type III prey are heavy and bulky and have large mass and girth ratios. Frogs, mammals, and some lizards are Type III prey. This prey type requires both immobilization and large gape.
4. Type IV prey are bulky and light, with small mass ratios and high girth ratios. Birds (which are bulky because of

their feathers) are Type IV prey and require gape specializations but not immobilization. Boas and pythons take Type III and IV prey, as do most of the advanced snakes (elapids, vipers, and colubroids).

The foraging behavior of snakes extends from active searchers that use visual or olfactory cues to find prey to mobile ambushers that move to places where they are likely to encounter prey. Rattlesnakes (*Crotalus*), for example, coil beside trails followed by rodents and wait for prey, and tropical racers (*Mastigodryas*) wait beside sunny spots on the forest floor to capture lizards (*Ameiva*) that pause to bask.

The exercise physiology of snakes appears to parallel differences in their foraging behavior. Widely foraging species, such as North American whipsnakes (*Masticophis*), have high aerobic metabolic capacities and high endurance, whereas species that rely on ambush (*Lichanura*) have lower aerobic capacities and endurance. Widely foraging species probably eat more often than ambushing species and take smaller prey, but even a frequent feeder such as the coachwhip snake (*Masticophis flagellum*) eats at 10-day intervals (Secor and Diamond, 1998), whereas most lizards probably eat daily.

Type III prey (heavy and bulky) can pose a risk of injury to a snake, especially to those species that swallow prey while it is still struggling. Constriction and venom are specializations that allow snakes to subdue a prey item before it is swallowed. Constriction is characteristic of primitive snake lineages and of boas and pythons. Apparently it evolved as a method of controlling elongate prey and subsequently proved effective with bulky prey as well. Constriction requires enclosing a prey item within coils of the snake's body. Little pressure is exerted on the prey, and friction between adjacent coils holds them in place. Death may result from asphyxiation (because the snake takes up the slack each time the prey exhales) or because increased internal pressure interferes and ultimately stops the action of the heart. The short-radius curves required for constriction require short vertebrae and trunk muscles that span only a few vertebrae. This morphology is not compatible with rapid locomotion, which requires large-radius curves formed by long vertebrae and muscles that span many vertebrae. The evolutionary appearance of advanced snakes in the Miocene coincides with the spread of grasslands. Constrictors (largely small boas) dominated the snake fauna at the beginning of the Miocene, but by the end of that epoch the snake fauna was composed largely of colubroids (in the sense of Zaher *et al.*, 2009). These were fast-moving snakes, but their locomotor specializations precluded constriction. Although some lineages of colubroids secondarily evolved constriction, venom is the distinctively colubroid method of immobilizing prey with minimum risk to the snake.

Venom evolved early in the history of colubroids as part of the feeding apparatus. The defensive use of venom is a secondary development, enhanced in some cases by morphological specializations. The venom channel in the fangs of spitting cobras, for example, makes an abrupt right-angle turn near the tip of the fang that enables the cobra to emit a spray of venom that travels a meter or more. The snake aims for the predator's eyes, and accounts by people who have been sprayed confirm the powerful deterrent effect of this defense. Attacking a venomous snake can have severe consequences for a predator, and the warning mechanisms of venomous snakes (such as the

rattle of rattlesnakes, the hood of cobras, and the distinctive colors of coral snakes) foster both learned and innate avoidance behavior by potential predators (Greene, 1988; Pough, 1988).

Duvernoy's gland, which lies at the rear of the maxilla and produces venom that immobilizes prey, is a derived character of colubroids. The embryonic development of Duvernoy's gland is linked to development of the posterior pair of maxillary teeth. These rearmost teeth are enlarged and grooved in many colubroids. Although colubroids are often called "the nonvenomous snakes" in popular literature, many colubroids use venom to subdue prey, and a few species known as rear-fanged snakes (notably the African boomslang, *Dispholidus typus*) can deliver defensive bites that are lethal to animals as large as humans. In the two groups popularly known as venomous snakes, elapids (cobras, coral snakes, sea snakes, and their relatives) and viperids (vipers and pit vipers), the maxilla has shortened, thereby moving the enlarged fang on the maxilla to the front of the mouth. Elapids have short fangs in a relatively immobile maxilla, whereas viperids have long fangs and the maxilla rotates so that the fang lies horizontally when the mouth is closed.

The venoms of elapids attack the nervous system and rapidly immobilize prey. In contrast, the venoms of vipers and pit vipers have high proteolytic activity and cause tissue destruction. The proteolytic activity of venom speeds digestion because the venom hydrolyzes the body tissues of the prey from the inside while the snake's digestive enzymes attack from the outside. Some vipers, especially species of the African genus *Bitis*, appear to combine proteolytic venom, injected deep into the prey by very long fangs, with modifications of the body-form to feed on very bulky prey. Large species of *Bitis* are remarkably heavy-bodied – length/circumference ratios of the puff adder (*B. arietans*) and Gaboon viper (*B. gabonica*) are 4 : 5. The thick bodies of these snakes accommodate bulky prey without disrupting locomotion or interfering with the function of internal organs.

The physiology of the digestive system of snakes is as specialized as their trophic anatomy (Secor, 2008). Large meals taken at infrequent intervals pose a challenge – the physiological cost of digesting a meal is high, but occasional periods of high activity are separated by long periods during which the digestive system is inactive. Within 24 h of feeding, snakes display remarkable factorial increases in rates of oxygen consumption; in the masses of organs in the cardiovascular, respiratory, digestive, and excretory systems; and in activities of digestive enzymes. Between feedings, the sizes of the organs and the activities of the enzymes regress to a resting state. This cyclic hypertrophy and regression, which is interpreted as a mechanism that conserves energy compared to the alternative of maintaining the physiological systems continuously at high levels, emphasizes the extent to which snakes display trophic adjustments that are shared by other vertebrates (Starck, 2003; Secor, 2005; Cox and Secor, 2008; Castoe *et al.*, 2008).

Conservation Issues

Many of the causes of declining populations of reptiles are depressingly familiar and affect other kinds of animals and plants as well. Habitat loss as a result of human activities is probably the major reason for shrinking populations,

although mortality on roads may be more significant than is generally recognized. Road kills are considered the major form of human-induced mortality for Australian reptiles and amphibians, exceeding the effect of habitat loss by nearly 70% (Ehmann and Cogger, 1985). Some European countries have built drift fences and constructed tunnels beneath roads to reduce mortality of reptiles and amphibians. Introductions of exotic species (especially on islands) and pollution (potentially including global warming (Dunham, 1993)) are additional factors that affect animals and plants on a large scale. Other threats are limited to particular groups and result from combinations of human activities and specific biological characteristics. For example, high-speed watercraft are a risk factor for crocodilians (Grant and Lewis, 2010).

Climate Change

Climate change affects the long-term persistence of populations of reptiles, as it does in other organisms, via changes in their biological and physical environments (Walther *et al.*, 2002). Most evaluations of climate change have focused on global warming, but climate change also encompasses decreased temperatures in some areas as well as changes in rainfall and in the intensity of solar radiation that reaches the Earth's surface, and global warming does not mean a uniform temperature increase everywhere or for every species.

For example, a change in cloud cover could lower the operative temperature of heliothermic reptiles while warming the average air temperature. An increase or decrease in the average ambient temperature could disrupt the match between seasonal cycles that are cued by day length, such as the timing of mating and egg laying, and cycles that depend on temperature, such as the appearance of plant growth stages or insect prey that provide the food needed by hatchlings. Similarly, changes in the amount or timing of rainfall could result in soil being too wet or too dry for successful egg development.

The ability of a species to resist the effects of climate change depends on a variety of factors (Packard and Packard, 2000; Morjan, 2003; Beeson and Cree, 2010, 2011; Doody and Moore, 2010). For example, changes in solar radiation or ambient temperature could exceed the ability of adult animals to alter daily or seasonal activity patterns to keep their body temperature within the range that permits normal activity. Nest temperatures or water potentials could exceed the limits for normal embryonic development, even if adults modify the seasonality of mating and egg laying and their selection of nest sites. Species with geographic ranges that do not permit migration, such as species living on islands, coral reefs, and near the tops of mountains are especially vulnerable to climate warming (Hamman *et al.*, 2007; Hawkes *et al.*, 2007; Bickford *et al.*, 2010; Fordham and Brook, 2010; Fouloupoulos *et al.*, 2011).

Although climate change is expected to decrease biodiversity, some species may benefit from the changed conditions. For example, the average body size of lizards, *Lacerta vivipara*, in four populations in southern France has increased over an 18 year period, apparently in response to a 2.2 °C increase in the daily maximum temperature during August, which is the first month after the lizards hatch (Chamaillé-Jammes *et al.*, 2006).

TSD is another aspect of reptilian biology that could be affected by climate change (Mitchell *et al.*, 2008; Kallimanis, 2009; Mitchell and Janzen, 2010). Long-term changes in nest temperature could bias sex ratios, and species in which the switch from one sex to the other occurs within a narrow range of temperatures might be especially vulnerable to the effect of global warming (Hulin *et al.*, 2009). A warming climate should increase the temperatures of nests, but the relationship between climate and sex determination may be complex. For example, the proportion of male hatchlings in a population of red-eared slider turtles increased from 2001 to 2004 despite a warming trend that resulted in earlier nesting by females (Tucker *et al.*, 2008). Apparently the low soil temperature of the early nests favored the production of male hatchlings, despite an overall warming trend.

The ability of a species to change its geographic range by migrating or changing elevation as climate changes is a critical factor in predicting the effect of climate change on species with temperature dependent sex determination (Araújo *et al.*, 2006). Some species might be able to mitigate the effect of climate change by altering their nesting season or nest-site selection (Doody *et al.*, 2006; Hawkes *et al.*, 2007; Schwanz and Janzen, 2008).

The effects of global warming on species with TSD may not be universally detrimental. For sea turtles, an increase in nest temperature by 2 °C would shift the proportion of hatchlings substantially toward females, and this change might be beneficial for some populations (Poloczanska *et al.*, 2009).

Turtles

Many species of turtles are long-lived and display a suite of coevolved traits, including delayed sexual maturity and high annual survivorship of adults (Congdon *et al.*, 1994). Adult turtles are often nearly immune from nonhuman predators, and a turtle that survives to adulthood can expect a long reproductive period. When adult mortality is increased by human activity, as is the case for sea turtles which are drowned at sea in the nets of shrimp trawlers and killed for food when they come ashore to nest, a crucial component of the life history strategy is destroyed. Sea turtles are the most visible examples of excessive adult mortality resulting from human activities, but automobiles kill adult turtles and tortoises all over the world.

Well-intentioned efforts at management can founder on aspects of the biology of a species. Sea turtles, for example, exhibit TSD – males are produced at low temperatures and females at higher temperatures. Conservation activities at the nesting beaches of sea turtles usually include moving the eggs from natural nests to a protected site where they are buried in the sand to complete incubation. Under these circumstances, all of the eggs are exposed to similar temperatures, and as a result the hatchlings will be predominantly one sex. Even worse, in some cases the incubation conditions used by management programs produced high proportions of male hatchlings.

The value of headstarting programs for turtles is unclear – do they increase survival of hatchlings (the most vulnerable life history stage) and do headstarted turtles become

reproductively competent adults? Some evidence for success can be found among the more than 20,000 tagged hatchling or yearling green turtles (*Chelonia mydas*) that were released from the Cayman Turtle Farm on Grand Cayman Island in the Caribbean between 1980 and 2001. A total of 392 of those turtles were recaptured between 1984 and 2001, and some of them had returned to nest on beaches near their sites of release (Bell *et al.*, 2005).

Crocodylians

The skins of crocodylians have long been used for expensive leather goods, and hunting has depleted many populations. The recovery of the American alligator, *Alligator mississippiensis*, following passage of protective legislation shows the potential for managing and restoring crocodylians. Success requires enforcement of laws and control of commerce, and these are difficult goals in many areas where crocodylians occur.

Some of the threats to crocodylians result from their semiaquatic life style. Like other large, slow-moving aquatic vertebrates, crocodylians are injured by collisions with watercraft (Grant and Lewis, 2010). The position of crocodylians near the top of aquatic food chains may make them susceptible to the effects of pollution. The pesticides dicofol, DDT, and their metabolites have reduced the hatching success and hatchling viability of alligators in Lake Apopka and have interfered with normal sexual development (Guillette *et al.*, 1994; Milnes *et al.*, 2008). Dicofol and DDT have estrogen-analogue properties and have affected the development of both sexes. Six-month-old female alligators from Lake Apopka had abnormal ovarian morphology and higher plasma levels of estradiol-17 β than females from the control site. Male hatchlings from Lake Apopka had abnormally small penises and plasma testosterone levels, only one-quarter of those of males from the control site.

Lepidosaurs

Most extant species of lepidosaurs are relatively small. Of course, small size does not protect a species, but it does tend to make its problems less conspicuous – and hence less appreciated – than those of animals like sea turtles and crocodylians. With a few exceptions, which have earned special status by being unique (e.g., tuatara) or colorful (the San Francisco garter snake, *Thamnophis sirtalis tetrataenia*), the status of populations of lepidosaurs is unknown.

Larger species of snakes and lizards are killed for food and for their skins. Professional hunters in Central and South America ship iguanas (*Iguana*) to food markets in the cities and collect tegu lizards (*Tupinambis*) for their skins. Monitor lizards (*Varanus*) are hunted for their skins in Africa and Asia. In 2000, almost 1.25 million live lizards and snakes and nearly 3 million lizard and snake skins were traded legally. Indonesia, Malaysia, Singapore, Vietnam, Sudan, El Salvador, Argentina, Columbia, and Paraguay were the largest exporters, and Japan, Germany, Spain, and the United States were the largest importers (World Resources Institute, 2007). The lizards and snakes hunted for the leather trade are large animals with long adult life spans and are high in the food chain.

There is little information about the status of wild populations of most of these species, but it seems unlikely that animals with these biological characteristics can withstand high rates of human predation indefinitely.

Glossary

Alvin Newly hatched salmon with unabsorbed yolk sac.

Anadromous Aquatic organisms that spawn and undergo early development in freshwater, migrate to sea to grow and mature, and return to freshwater to reproduce.

Fry Juvenile salmon that have absorbed their yolk sac and emerged from the gravel.

Grilse Atlantic salmon that spends only 1 year at sea before returning to spawn.

Iteroparous Aquatic species that can spawn more than one time.

Jack A sexually precocious male salmon that spends one winter or less at sea before returning to its natal stream to spawn.

Kelt A spawned out Atlantic salmon or steelhead that is returning to the ocean to recuperate, sexually mature, and spawn again.

Parr Older juvenile salmon that are distinguished by parr marks – prominent oval spots on their sides.

Semelparous Aquatic species that die after reproduction.

Smolt A downstream migrating salmon that has begun the physiological transition to seawater.

Introduction

The Pacific and Atlantic salmon are a diverse group of fish distributed throughout the Northern Pacific and Northern Atlantic Oceans and their adjacent freshwater coastal habitats. The Pacific Salmon include seven species in the genus *Oncorhynchus*: pink (*Oncorhynchus gorbuscha*), chum (*Oncorhynchus keta*), sockeye (*Oncorhynchus nerka*), coho (*Oncorhynchus kisutch*), and Chinook (*Oncorhynchus tshawytscha*) salmon are found in North America and throughout the Pacific rim; masu (*Oncorhynchus masou*) and amago (*Oncorhynchus amago*) salmon are found only in Asia. In addition, there are two trout members of the genus *Oncorhynchus* that have anadromous forms: steelhead (*Oncorhynchus mykiss*, the anadromous form of rainbow trout) and the sea-run cutthroat trout (*Oncorhynchus clarkii*). There is a single species of Atlantic salmon (*Salmo salar*). This article focuses on the anadromous salmonids of North America, and their long history of decline in abundance and diversity.

Classification

Over the past two centuries, fish have been the subject of extensive systematic research and countless taxonomic revisions – and among the some 24 000-plus named species of fishes, the salmonids have been no exception. Currently, the salmonids are members of the class *Osteichthyes* (the bony fishes), the subclass *Actinopterygii* (the ray-finned fishes), the

division *Teleostei*, and the super order *Protacanthopterygii*. The *Protacanthopterygii*, which contains some 310-plus species, is divided into three orders: the *Salmoniformes* (the salmonids), the *Esociformes* (the pike and mudminnow), and the *Osmeriformes* (the smelts). There are about 70 species in the family *Salmonidae* (order *Salmoniformes*), which can be divided into three subfamilies: *Salmoninae* (salmon and trout), *Coregoninae* (whitefishes), and *Thymallinae* (graylings).

According to Behnke (1992), the earliest fossil record of the salmonids is *Eosalmo driftwoodensis*, which was discovered in Eocene deposits some 40–50 million years ago in British Columbia. The separation of the Atlantic Ocean group (*Salmo*) and the Pacific Ocean group (*Oncorhynchus*) likely occurred by the mid-Miocene about 15 million years ago. By the end of the Miocene (about 5 million years ago), the ancestral form of *Oncorhynchus* in North America evolved into two distinct lineages, one leading to the Pacific salmon and the other to the Western trout. The evolution of Pacific salmon is still the subject of scientific debate. Particularly intriguing is the question of whether salmon evolved first in freshwater, only later developing the ability to migrate to the ocean, or whether they evolved first as marine species that later developed the ability move into freshwater refugia to spawn and rear. No matter which the case, the currently recognized species are generally believed to have differentiated only 500 000 to 1 million years ago, which represents an extremely short time period for such extensive speciation to occur. Rapid speciation was probably favored by the geological and climatic history of North American landscape – constantly being shaped and

reshaped by volcanism, alternating periods of warm and cold climate, alternating arid and pluvial periods, and rearrangement of major drainage basins.

The classification of North American salmonids does not stop with the traditional Linnaean system of classification for plants and animals. In particular, salmonids have been classified into evolutionary significant units (ESUs) or distinct population segments (DPSs) to facilitate risk assessments under the federal Endangered Species Act. The ESU and DPS are for all practical purposes the same. By definition, an ESU is any group of populations that is distinct according to two criteria: (1) It must infrequently exchange genes with other conspecific population units; and (2) It must represent an important component in the evolutionary legacy of the species (Waples, 1995). The concept of the ESU and DPS as a fundamental unit of conservation under the Endangered Species Act has been reviewed and endorsed by the National Research Council (1995) and is an important landmark in evolutionary thinking applied to conservation. This is because the ESU emphasizes genetic structure and life history adaptation as a focus for protection as opposed to more typological definitions of species or subspecies based on appearance.

In Western North America, 52 distinct salmonid ESUs or DPSs have been identified, with 27 of them currently listed as threatened or endangered under the Endangered Species Act. On the East Coast of North America the Atlantic salmon Gulf of Maine DPS is listed as endangered.

Life Histories

Salmon and anadromous trout display an amazing variety of life history patterns, both among and within species. However, many features are held in common. The life cycle begins with females depositing eggs in nests or redds in gravel bottoms of rivers and lakes. The young emerge from the gravel as alevins or fry to rear in freshwater for periods varying from a few days to several years. As juveniles or parr approach the time for their seaward migration, they undergo physiological metamorphosis or smoltification during which, among other changes, they develop the ability to osmoregulate in the hypertonic marine environment. In the ocean, they often undertake extensive migrations, covering many thousands of miles, while they grow and mature. After periods that range anywhere from a few months to 4 or more years, adult salmon return with remarkable fidelity to their natal river and tributary to spawn and continue the cycle.

The key characteristic that distinguishes the Atlantic salmon and anadromous trout from the five species of Pacific salmon is the fact that Pacific salmon species are semelparous and die after spawning only once, whereas anadromous trout and Atlantic salmon are iteroparous and may spawn multiple times. As is evident in the ensuing sketches of species-specific life history traits, diversification among salmon primarily has involved permutations that alter the schedule and timing of freshwater versus ocean habitat use (Busby *et al.*, 1996; Groot and Margolis, 1991; Shearer, 1992; Trotter, 1989).

Pink Salmon (Also Known as Humpback Salmon)

Pink salmon, which are distributed throughout the North Pacific and Bering Sea north of 40° N, are the most abundant of the Pacific salmon. In North America, pink salmon spawn from August to November and generally return at smaller sizes than other salmon – ranging between 1.0 and 2.5 kg. Returning adults undergo only modest migrations, often spawning in intertidal areas. After emerging from the gravel, they swim directly to sea, where they migrate and feed extensively in the North Pacific. After 18 months at sea, they return to their river of origin to spawn and die. This fixed 2-year cycle leads to the genetic isolation of what are referred to as odd- or even-year runs. Typically, different geographic regions are dominated by odd- or even-year runs, but not both. The tendency of having only one type of run (odd or even) in each river may exist because the rivers are not productive enough to support spawning by pink salmon every year.

Chum Salmon (Also Known as Dog Salmon)

Chum salmon are second only to pink salmon in abundance, but because of their large size they comprise up to 50% of the marine biomass of salmon in the North Pacific. Historically ranging from the San Lorenzo River in California to the Mackenzie River on the Beaufort Sea to the north, returning adults can weigh as much as 20 kg. Like pink salmon, chum salmon tend to spawn low in river systems and migrate quickly to estuarine and marine waters, often spending extended periods rearing in estuarine habitats. Once offshore, chum salmon are widely distributed throughout the North Pacific, typically spending 2–5 years at sea, but occasionally as long as 7 years. There are two generally recognized races of chum salmon, which are distinguished by their time of return to freshwater: Early and late stocks, or summer- and fall-runs, with the fall-run populations far more prevalent.

Sockeye Salmon (Also Known as Red Salmon)

Sockeye salmon are the third most abundant of Pacific salmon, comprising 17% by weight and 14% by number of the salmon total. They display a wide variety of life history patterns, including a subspecies that spends its entire life in freshwater – the kokanee. The vast majority of sockeye salmon populations spawn either in tributaries associated with lakes or directly in lakes on gravel shoals. After emerging from the gravel, the juvenile sockeye salmon spend from 1 to 3 years rearing in lakes. There are, however, rare populations that spawn in the rivers not associated with lakes and populations that migrate directly to sea shortly after emergence from the gravel. Like the other salmon species with extended freshwater rearing, smolts tend to move quickly downstream, spending little time in the estuarine and near-shore habitats and are found widely distributed throughout the North Pacific Ocean. Adults typically spend 1–4 years at sea, before returning to spawn in their natal lakes and tributaries. Maturing adults enter freshwater from late spring to early summer, with spawning occurring from late July through January.

Coho Salmon (Also Known as Silver Salmon)

Coho salmon are the most widely distributed of the Pacific salmon, but they are the least abundant. The vast majority of the populations have a 3-year fixed cycle – spending about 18 months in freshwater and 18 months at sea. In North America, they range from Monterey Bay, California, in the south to the Krupuk River in Alaska. Coho salmon typically enter freshwater from August to January and quickly move upstream to spawn in coastal streams and the smaller tributaries of large river systems. After emergence from gravel, juveniles rear in the smaller tributaries, and overwinter an additional year before beginning their seaward migration during the spring of their second year of life. At sea, coho salmon tend to stay on the continental shelf, feeding and growing in marine waters at roughly the same latitude as their stream of origin.

Chinook Salmon (Also Known as King Salmon)

Chinook salmon are the largest of the Pacific salmon – returning at weights up to 45 kg. In North America they range from central California to Kotzebue Sound, Alaska, and spawn in diverse habitats ranging from tidewater to small tributaries located as far as 3200 km inland. Locally, runs tend to be identified by the time at which adults enter freshwater and begin their spawning migrations, hence the colloquial names spring-, summer-, fall-, late fall-, and winter-run Chinook salmon. However, these designations do not capture the true biological diversity of this species.

Along with sockeye salmon, Chinook salmon display the greatest within-species variation in life histories of all the Pacific salmon, including variation in age at seaward migration, variation in duration of freshwater, estuarine, oceanic residency, variation in ocean distribution and oceanic migratory patterns, and variation in age and season of spawning migration. This variation is derived from two sources, one racial and the other environmental. The racial differences result from geographic and hence genetic isolation that divides Chinook salmon populations into one of two behavior forms, stream-type and ocean-type. Stream-type populations spend 1 or more years in freshwater before seaward migration; undertake extensive offshore migrations, and return to their natal streams during the spring or summer, often holding in freshwater for several months before spawning in late summer. In contrast, populations of ocean-type Chinook salmon migrate to sea before age 1, utilize estuarine and near-shore habitats for extended periods, often spending their entire ocean residence on the continental shelf, and return to their natal stream in the fall immediately before spawning. A second major source of life history variation in Chinook salmon is expressed as run-timing, age at outmigration, and age-at-spawning differences within races, within populations, and sometimes even within cohorts. For example, it has only recently been found that ocean-type fall Chinook salmon originating in the Snake River (Columbia River basin) display not only the typical pattern of subyearling migration, but also some variable proportion of a year class will also overwinter in the riverine environment and migrate to the ocean as yearlings the following year (Connor *et al.*, 2005). The adaptive value of such variation is well known in evolutionary theory – by

spreading the timing of migration and spawning among years, these fish are effectively “spreading the risk” and reducing the likelihood of total failure if any single year or even week is disastrous (the argument works at a variety of temporal and spatial scales). Uncertainty in juvenile survival and marine productivity is enormous for salmon, and this is reflected by the fact that year-to-year variability in spawner counts for salmon (see Figure 1) have coefficients of variation typical of pest insects and other notoriously fluctuating species.

Atlantic Salmon

Atlantic salmon are the only anadromous salmonid native to the Atlantic coast of North America. Historically found in nearly every major coastal river north of the Hudson River, the extinction of several U.S. populations by the end of the nineteenth century has shifted the southern extent of the species distribution over 200 km northward. The majority of adult Atlantic salmon enter freshwater to spawn during the spring (late May to early June primarily), spending most of the summer holding in freshwater and then spawning in fall. In general, the more northern populations arrive earlier, and spawn earlier. However, a few populations do not enter freshwater until late summer or early fall, bypassing the summer holding period and consequently spawning directly. Juvenile Atlantic salmon emerge from the gravel in the spring and typically spend from 2 to 4 years rearing in freshwater (although some populations spend as little as 1 year and others as much as 8 years in freshwater). Outmigration of juveniles usually occurs from April to mid-June, with the smolts spending little time in the estuarine and near-shore zone. Atlantic salmon are widely distributed in the North Atlantic, with American and European stocks often concentrating and mixing in the waters off Greenland – a distribution which enabled the development of highly efficient commercial fisheries that nearly drove the species to extinction in the 1960s. The majority of Atlantic salmon spend two winters at sea before returning to spawn.

Steelhead

There are two major genetic groups of *O. mykiss* presently recognized in North America: the *inland group* and *coastal group*, with the distinguishing character being their use of freshwater habitat. As the name implies, the coastal form populates the wet coastal regions of western North America, whereas the inland form is found in the more arid interior regions of western North America. Both forms occur in British Columbia, Washington, and Oregon; Idaho has only the inland form, and California has only the coastal form. Both forms display a wealth of life history variation, including an anadromous form that is known as steelhead. Although steelhead can be observed entering freshwater to spawn throughout the year, they usually display striking seasonal peaks in spawning activity. This has resulted in the use of seasonal run timings to distinguish different populations (fall-run, summer-run, etc.). Steelhead can be divided into two basic reproductive ecotypes based on their state of sexual maturity at the time of river entry and the duration of

Figure 1 Counts of spring/summer Chinook salmon returning to four Salmon River tributaries, 1957–2008. Note that returns before the late 1970s were substantially higher than subsequent years. This abrupt decline coincided with completion of eight dams between the spawning grounds and the ocean; construction of several major hatcheries and the release of large numbers of hatchery fish; and a major shift in ocean conditions. In both the early 1980s and mid-1990s several Snake River populations were clearly at risk of extinction, but have since shown signs of rebuilding.

spawning migration. The stream-maturing type (commonly known as fall steelhead in Alaska, summer steelhead in the Pacific Northwest and northern California) enters freshwater in a sexually immature state and spends several months maturing before they spawn. In contrast, the ocean-maturing type (spring steelhead in Alaska and winter-run elsewhere) enters freshwater in a sexually mature state and spawns shortly thereafter. While many rivers contain populations of both ecotypes, coastal streams tend to be dominated by winter steelhead, whereas inland reaches tend to be predominately the summer steelhead.

Despite the major differences in migration timing of the adults, both ecotypes of steelhead generally spawn from December through March. After emerging from the gravel in late spring, juveniles spend up to 7 years in freshwater, with 1–3 years being the norm. Most populations in Alaska and British Columbia tend to smolt and migrate to sea at 3 years of age, whereas the more southern stocks tend to smolt at 1 or 2 years of age. Most North American steelheads spend 2 years at sea; however, some of the more southern stocks characteristically spend only 1 year at sea. An unusual variant in life history found among selected steelhead populations in Southern Oregon and Northern California is that of the half-pounder. Half-pounders are juvenile fish that migrate to sea, only to return to freshwater in an immature state after only 2–4 months. The biological basis for this unusual behavior is unknown. As an iteroparous species steelhead can spawn multiple times, with the frequency varying both within and among populations. The more northern populations tend to have a lower proportion of repeat spawners than those further south.

Sea-Run Cutthroat Trout

Cutthroat trout display a complex suite of life histories – some exclusively freshwater and others involving a period of marine residency. While it is the latter life history strategy that justifies their inclusion in this article, the reader should be aware that the interrelationships between the different life history variants are not fully understood, and sea-run forms probably cannot be treated as isolated from the freshwater forms (Trotter, 1989).

In North America, sea-run cutthroat trout are distributed along the Pacific Coast from the Eel River in California to Prince William Sound in Alaska. Adults typically spawn in the small tributaries of low-gradient streams and the lower-gradient downstream reaches of large river systems from late winter to late spring. Juveniles rear in freshwater for 2–4 years, generally utilizing slower moving waters and pools. Those populations that migrate into the protected waters of large estuaries and sheltered bays tend to smolt at age 2, whereas those populations migrating into the near-shore ocean often delay smoltification until age 3 or 4. Sea-run cutthroat trout seldom spend more than a few months in marine waters and stay well within the near-shore zone, typically returning to freshwater in late summer, fall, or winter of the same year they migrate to sea. Although fish returning to freshwater to spawn return to their natal stream with high fidelity, non-maturing fish are known to leave the ocean and overwinter in nonnatal streams. Like steelhead and Atlantic salmon, sea-run cutthroat are iteroparous, and multiple spawning is quite common.

Special Salmon Adaptations

Anadromy

Anadromous fishes are those that spawn in freshwater, migrate to the ocean to forage and mature, and return to freshwater to spawn and begin the cycle again. As anadromous species, the salmonids pass through multiple habitat transitions and face major physiological challenges – the most critical adaptation for this lifestyle is the ability to osmoregulate in both freshwater and marine environments, and to do so at precisely prescribed times. The evolution of anadromy has intrigued biologists for as long as salmon have been studied. Although many theories have been put forth to explain the evolution of anadromy, such a major life history character must, on balance, provide an overall advantage to individual fish. The potential advantages of anadromy include (a) a mechanism for dispersal and rapid recolonization of regions suddenly made available to fish (such as the retreat of a glacier); and (b) being able to get the “best of two worlds” (freshwater and marine). The “best” of the freshwater world involves reduced predation on eggs and juvenile fish because the embryos develop in the protected environment of gravel until they emerge at a large enough size to actively avoid stream-dwelling invertebrate predators. The “best” of the marine world involves higher growth rates for larger maturing fish in the oceans, made possible because in upwelling areas and years of high productivity the regions of the ocean frequented by salmon provide an abundance of larger prey items that far exceeds the prey base of most freshwater ecosystems.

Homing

The legendary ability of Pacific and Atlantic salmon to home with high fidelity to their stream of origin is one of the more spectacular migrations in nature. Beginning with the pioneering work of Hasler, Quinn, and others, it is growing increasingly clear that this ability involves a combination of magnetic detection, solar navigation, and olfactory cues. The salmon’s ability to navigate the high seas appears to be based on the ability to detect inclination and declination of the earth’s magnetic field, combined with celestial orientation and an “endogenous circannual rhythm, synchronized by day length or rate of daylight change to sense latitude” (Quinn, 1982). Once in the vicinity of their home stream, it appears that salmon homing is facilitated by following unique gradients of odors that are learned during the downstream migration of juveniles.

Despite uncertainty about the exact mechanism of homing, the fact that salmon return to their natal streams is ecologically quite significant. From a very practical perspective, it assures that salmon return to an area with favorable spawning and rearing conditions. In addition, although often considered a failure in homing, the small proportion of salmon in a population that stray to neighboring streams play an important role in the colonization of vacant habitat. Such a nearest neighbor strategy is more likely to be successful in matching salmon with habitat than a random pattern of straying, and hence it is a more efficient means of reestablishing sustainable populations.

Historical Status and Overview of Decline

Historically, spawning populations of Atlantic salmon were abundant in most rivers and their tributaries throughout Europe, the British Isles, and the Baltic North, and in all the major North America rivers north of the Hudson River along the Atlantic seaboard. Likewise, the thousands of rivers and streams dissecting the coastal lands surrounding the North Pacific Ocean supported major populations of Pacific salmon and anadromous trout. Today, however, these once plentiful species are greatly reduced in both abundance and distribution. Owing largely to the actions of humans and the encroachment of “civilization,” populations of Atlantic salmon throughout much of Europe and in New England have all but disappeared from the landscape. Similarly, in the Pacific Northwest, only a fraction of the streams and rivers that once supported robust salmon populations continue to do so. Although there are some obvious differences, there are also some striking similarities in the causes and patterns of decline of Pacific and Atlantic salmon – in Europe the onset of the Industrial Revolution, in New England the colonization by European settlers, and in the Pacific Northwest the arrival of the Euro-American settlers. The 1991 review of Nehlsen *et al.* perhaps best captures the status of salmon in the Pacific Northwest by noting that, of 214 individual populations of native naturally spawning populations of salmon in California, Oregon, Idaho, and Washington, 101 were at high risk of extinction, 58 were at moderate risk of extinction, and 54 were of special concern. The situation has become so dire that the 27 federally listed endangered and threatened salmonid ESUs and DPSs span almost every major freshwater ecosystem from the Sacramento River northward, with vast political and social consequences for the western United States.

Habitat, Harvest, Hatcheries, and Hydropower as Major Threats to Salmonid Diversity

Many factors, both natural and human caused, are major sources of mortality among populations of North American salmon. While there is a handful of examples of a single factor causing populations to go extinct (e.g., a dam completely blocking access to spawning and rearing habitat), more often than not there is a constellation of factors that place salmon at risk of going extinct. An extremely thorough review of the current status of Pacific Northwest salmon and the factors contributing to their decline was recently published by Lichatowich (1999). In *Salmon without Rivers*, Lichatowich chronicles the methodical extirpation of one salmon population after another as the Euro-American settlers and their industrial economy replaced what he refers to as the “gift economy” of the native Indian tribes. Given the widespread destruction of habitat and a “modern” harvest philosophy built on the false premise of unlimited productivity, it is indeed amazing we still have viable populations of salmon in the Pacific Northwest.

The human-caused threats to salmon are often described in a framework of the four Hs: habitat, harvest, hatcheries, and hydropower. This convenient framework is followed here, but it is also a little misleading in how it categorizes risk factors in

tidy compartments. For example, while it has been traditional to view habitat threats as freshwater and affected only by human destruction, this view grossly neglects the importance of estuarine and marine habitats and the role they play in salmon productivity. Further, while there is a tendency to dismiss the ocean as a homogeneous “black box” that is unaffected by human activities, there is likely to be a strong interaction between some of the Hs such as hatcheries and ocean conditions. For example, the industrial-scale production of hatchery fish in large river systems such as the Columbia River Basin may not be problematic except during periods of low primary and secondary productivity in the near-shore ocean. Hatchery and naturally produced smolts may compete only during periods of low ocean productivity. In addition, the ill effects of individual fitness compromised by gene flow from hatchery fish may be felt only if wild fish are already stressed by poor ocean conditions.

Habitat

The destruction of freshwater habitat is perhaps the single most significant factor affecting Pacific and Atlantic salmon in North America. Logging, mining, and agriculture (including grazing, irrigation withdrawals, soil erosion, and chemical contamination) have been major causes of salmon decline. While many of the impacts of these activities are similar, some are unique. For example, the logging practices of the past two centuries has caused widespread destruction of riparian vegetation along stream corridors (producing increased in-stream temperatures) and has caused landslides due to poor road-building practices (resulting in sedimentation and destruction of spawning and rearing habitat). Other impacts, such as the creation of thousands of acres of impermeable surfaces, are unique to urbanization. While it is beyond the scope of this article to describe in detail the nature of all of the different forms of habitat destruction, it is important to note that most are clearly the product of human actions and hence controllable.

Harvest

Pacific and Atlantic salmon have been the target of harvest by the indigenous peoples of North America for many thousands of years. However, it was not until the early- to mid-1800s that the Euro-American settlers (with their advanced methods of capture and preservation) began to so overfish salmon that extinction became a possibility. Particularly destructive have been offshore fisheries that indiscriminately harvest mixtures of plentiful hatchery fish and dramatically less abundant wild fish. Although harvest is currently regulated to some extent, it still continues at substantial rates, even on endangered and threatened ESUs. For example, fall Chinook salmon from the Snake River are currently harvested at an annual rate that exceeds 20%, and some listed ESUs in the Puget Sound area are harvested at annual rates that exceed 40%. Fish taken by harvest represent individuals with maximum reproductive value and the impact of their mortality before spawning is unarguably large. It may be that the models guiding our harvest policy are themselves flawed, as suggested by recent theoretical papers which suggest that harvest models built with

Figure 2 Analysis of the benefits of a temporary moratorium on harvest for Snake River fall Chinook salmon. A simple age-structured model iterates salmon populations forward 20 years, using estimates of variability and recruitment from 1980 onward. Two alternative simulations are run: simply continuing to harvest at the current rate versus halting harvest for 10 years and then reinitiating harvest for years 11 through 20, but at 75% of the current rate. Note that if there is a 10-year moratorium followed by harvest at 75% of the current rate, the population rebuilds and total cumulative harvest after 20 years (even including 10 years without any harvest) ends up being higher than if current practices are continued. One may be able to have fish and harvest, if harvest is temporarily halted.

the concept of an optimum percentage take and maximum sustained yield often fail in highly variable environments (Lande *et al.*, 1997; Ludwig, 1998). The good news is that simple models suggest that threatened ESUs such as Snake River fall Chinook salmon may be readily rebuilt by temporarily curtailing harvest – indeed with only a 10-year moratorium populations may recover sufficiently to then sustain a vigorous harvest that annually yields double the number of fish currently removed from the river (Figure 2). Certainly, the issue of harvest for these threatened stocks needs to be reevaluated – for perspective, it is hard to imagine anyone tolerating the hunting of threatened whales at a rate leading to 20% adult mortality per year, given the status of whales as listed under the Endangered Species Act.

Hatcheries

The building of hatcheries and the production and release of millions of hatchery salmonids in the Pacific Northwest

closely tracked the wholesale destruction of habitat and overfishing. Indeed, hatcheries were widely viewed as the solution – and in fact a solution that facilitated the extraction of natural resources to proceed unchecked. It was not until the past several decades that biologists began recognizing that such use of hatcheries were, by themselves, a potential problem. Beyond the obvious creation of harvest opportunities and destructive mixed-stock fishing, there is now much greater recognition that the release of large numbers of hatchery fish can have detrimental ecological and genetic effects on natural populations.

Ecological impacts of the release of large numbers of hatchery fish include intra- and interspecific competition for food and space among hatchery and wild salmonids, predation by larger hatchery salmonids on their wild counterparts, transmission of infectious diseases from hatchery to wild salmonids, and altered migratory behavior of wild fish caused by the timing and magnitude of hatchery releases (reviewed by Flagg *et al.*, 2000). While many of these interactions were believed limited to the freshwater environment, a recent study suggests density dependent interactions between wild and hatchery salmonids in the marine environment as well (Levin *et al.*, 2001). The potential for density dependent competition in the marine environment was further highlighted in a recent analysis of trends in the combined abundance of adult pink, chum and sockeye salmon in the North Pacific Ocean (the three most abundant salmonid species). Ruggerone *et al.* (2010) compiled data indicating that combined abundance of these species doubled from 309 to 636 million over the past 50 years, with 22% of total attributable to hatchery releases of chum salmon.

Other recent studies indicate that some species of hatchery-origin salmonids, when they spawn in the natural environment, have reduced intrinsic productivity compared to that of their wild counterparts, and that the overall productivity of a mixed hatchery–wild population decreases as the proportion of hatchery fish increases. For example, Fleming and Gross (1993) and Araki *et al.* (2007) reported reduced reproductive fitness of coho salmon and steelhead due to genetic and environmental effects on size at maturation, run-timing, behavior, and other possible traits. Williamson *et al.* (2010) documented that hatchery-origin spring Chinook salmon in a tributary of the Columbia River produced about half the juvenile progeny per parent when spawning naturally than did natural-origin fish. To the extent that the reduced reproductive fitness is heritable, there is an obvious long-term potential for hatchery fish to eventually reduce the fitness of wild populations. Collectively these studies raise serious questions about the potential use of hatchery programs to supplement and contribute to the rebuilding of sustainable salmon populations.

Hydropower

Dams block access to spawning habitats, create reservoirs that flood spawning habitats, and may stress fish migrating through them to such a large extent that females cannot replace themselves due to depressed physiological fitness. Dams affect both upstream adult spawning migrations and downstream juvenile migrations. Primary mechanisms for the

negative impacts of dams involve increased mortality of juveniles associated with passage through turbines, atmospheric gas supersaturation, and decreased flow and turbidity. On the other hand, engineering improvements in dams can mitigate some of these effects, although certainly not to the extent that rivers return to the equivalent of their free-flowing natural state. Because dams are the most visible impediment to salmon survival, getting fish around, over, or through dams has been the focus of much research. Unfortunately, the understandable focus on hydropower as a risk factor for salmon has left the “other Hs” less well studied. Recovery of salmon is likely to often require more than simply removing dams – we may also need improvements in spawning habitats and in ocean and estuarine environments, further reductions in harvest, and perhaps major modifications of hatchery programs. Finally, it is worth pointing out that although removal of dams is often championed in terms of “returning to a normative river” (Independent Science Group (ISG), 1999), most proposed dam removals still leave many dams untouched and our rivers so altered by other factors that they remain a long way away from the ideal of a free-flowing “wild river.”

Natural Environmental Variability and Climate Change

Although the tendency in recent years has been for resource managers to focus on the human-caused factors that have contributed to the decline of salmon, natural variation in environmental conditions, both freshwater and marine, are also major factors affecting the abundance and distribution of salmon. Operating on seasonal, annual, and decade-long timescales, events such as regime shifts, El Niños, and changes in seasonal patterns of coastal circulation (particularly upwelling) all can have a profound effect on oceanic survival of salmon. Particularly noteworthy has been the research documenting correlations among broad patterns of productivity, and major physical features of the ocean–atmosphere interaction. For example, Hare *et al.* (1999) found that harvest (and presumably abundance) of Pacific salmon in Alaska has varied inversely with catches along the U.S. West Coast over the past 70 years. In exploring various explanations for this observation, they found a striking correlation between switching pattern of north–south abundance and the Pacific decadal oscillation (PDO; a recurring pattern of pan-Pacific atmosphere–ocean variability). While there are several ocean–atmosphere indices such as the PDO, they all, in concept, attempt to capture the key physical forces that drive decadal-scale basin-wide climate variability. For example, since the last major climate shift of 1976–77 in the North Pacific Ocean, oceanographers have documented decreased mixed-layer depths in the Subarctic Gyre and increased sea surface temperatures along the west coast. The biological responses to these physical changes were profound, including major changes in primary and secondary production, and micro- and mesoscale changes in zooplankton biomass and species composition. In addition to salmon, a large number of higher trophic level fish, birds, and mammals show similarly dramatic shifts in abundance and distribution coincident with these changes in ocean conditions.

Operating on an even grander scale, the impacts of long-term climate change will undoubtedly have profound consequences for all animal and plant species. Indeed, climate change is perhaps the most complex environmental and conservation challenge of the 21st century. Salmon, because of their anadromous nature, will suffer the dubious distinction of being subject to impacts in both the marine and freshwater habitats – a distinction that may well challenge their ability to adapt and survive over much of their current range. In the freshwater phase of their life cycles, salmonids in many areas will likely face major changes in temperature and precipitation patterns that will greatly alter the quantity and quality of habitat in ways that will challenge their ability to survive and adapt. This will likely profoundly affect their range and productivity over a latitudinal gradient. Climate change is also expected to depress oceanic productivity by disrupting upwelling patterns in a way that reduces the delivery of nutrients (Bakun, 1990). To the extent that salmonid population fluctuations are determined by bottom-up forces, the possibility of reduced coastal nutrient upwelling and warming conditions of offshore habitat could have dire consequences for these and many other fish species. All of these changes will require resource management and conservation policies that are robust to change, and adaptable to a changing environmental baseline (Schindler *et al.*, 2008).

Of the many studies designed to predict the consequences of climate change on aquatic species, one of the more dramatic is Welch *et al.* (1998). To explore potential marine impacts on salmon, Welch and colleagues compiled an extensive data set on distribution of salmon at sea and found that, for sockeye salmon, marine distribution was limited by sharp thermal boundaries. Using a climate model, and assuming a doubling of greenhouse gases over the next 50 years (which is consistent with the current rate of input), it was predicted that sockeye salmon would be excluded from most of the Pacific Ocean and restricted to a relatively small area of the Subarctic Pacific for much of the year. Similar analyses revealed marked reduced ocean habitat for other species of Pacific salmon as well.

What is the Value of Salmonid Biodiversity and Can We Rescue Salmon from Extinction?

Two arguments dominate the mainstream ecological literature regarding the “value of biodiversity”: (1) diversity fosters enhanced productivity by allowing a more complete exploitation of the environment *via* a variety of different forms, each adapted to different habitats or resources, and (2) diversity fosters enhanced stability by spreading the risk and providing redundancy in the face of unpredictable catastrophes. Both hypotheses regarding the value of biodiversity apply well to salmon. First, different salmonid ESUs spawn in different portions of the freshwater environment (inland versus coastal, mainstream rivers versus streams, lakes versus rivers, and so forth) and migrate to different regions of the ocean. Any loss of salmonid diversity would mean that the productivity of these ecosystems would be reduced, with minimal likelihood that any other species could take the place of salmon (since the anadromous lifestyle is so unique). Second, due to

climatic fluctuations, different months of the year will be favorable for migration; in fact, recent data indicate that even a shift of a few days with respect to the time at which juvenile Chinook salmon arrive at the ocean can alter survival rates by a factor of two. If salmon diversity is reduced, then there will be less variety in run-timing and life history schedule and consequently much less insurance against the vagaries of climatic fluctuations. The precipitous decline of Pacific and Atlantic salmon throughout much of their range raises a number of important questions: Can we save the salmon? Should we save the salmon? And what do we need to do to save the salmon?

Can We Save the Salmon?

The answer to this question is an unequivocal yes. A species complex that has survived and flourished under the wide range of conditions from which salmon have evolved has almost certainly weathered numerous survival bottlenecks in the past, caused by environmental perturbations ranging from volcanic eruptions to the total loss of huge blocks of habitat to glaciers, fire, and floods. Perhaps the key attribute that has allowed the salmonids to survive these events is the tremendous diversity of life histories and patterns of habitat use. The salmonids represent a plastic species complex with a robust evolutionary potential that should facilitate survival under diverse conditions.

That said, many populations in the Pacific Northwest and Northeast North America are already extinct, and many others have never been at lower levels of abundance. Saving Pacific and Atlantic salmon will clearly require immediate action that will include economic sacrifice, societal discipline, and a commitment to a science-based recovery strategy – all at a very significant cost to the people of the affected regions.

Should We Save the Salmon?

Because of the societal implications and costs, this question perhaps extends well beyond the boundaries of biology. However, from strictly an ecological perspective, the salmonids are a vital component of the North Pacific and North Atlantic ecosystems and the associated coastal habitats. The ecological importance of salmonids as predators, prey, and nutrient recyclers is obvious to even the most casual observers of nature. While as scientists we can marvel at the complexity of an ecosystem and strive to understand species and environmental interactions in the broadest sense, we must also acknowledge that such complex and dynamic systems may never be fully understood. Nonetheless, the loss of such a key species complex as salmonids over such a broad geographic area would no doubt be a biological event without precedent.

What Do We Need to Do to Save the Salmon?

As noted earlier, the keys to solving the salmon problem are societal commitment, discipline, and a science-based recovery strategy. While societal commitment and discipline are not scientific issues, they certainly are not devoid of science. To make a decision on whether and how to proceed, society must

have knowledge – knowledge of the complexity of the problem and the certainty (or lack thereof) associated with various courses of action. This knowledge is vital to the economic decision-making process.

In contrast, the design of recovery strategies is largely a science issue. At the core of every science-based recovery strategy should be an analytical framework that allows: (1) the methodical determination of survivorship in each of the life history stanzas of salmon, (2) the identification of actions and opportunities to increase survivorship, (3) the assessment of biological (and societal) feasibility of each action or suite of actions, and (4) a rigorous monitoring and evaluation plan. Whatever models are used should be clear and understandable to the average citizen, and data used as model inputs must be available to all.

Clearly, society cannot continue the extraction-based economy of the past 200 years and expect even remnant populations of salmon to exist over even a fraction of their former range. A major shift in environmental decision making will be required. In particular, we must abandon the habits of the past two centuries, which have involved almost universally approaching conservation through a “reduction from the status quo” perspective, and the belief that we can replace lost production with hatchery programs. For example, rather than arguing about whether we should reduce harvest by 10, 20, or even 50% from current levels, any harvest above 0% should require a scientifically sound justification. Moreover, rather than rely on artificial production to replace natural production from diverse habitats, the focus should be on restoring those lost habitats in a spatially and ecologically meaningful pattern. When populations face a high probability of extinction, modest adjustments of the status quo are not enough. Unless society seriously acts to rebuild salmon populations, the future of salmon is not assured, and moderate actions ought to be recognized as optimistic gambles (as opposed to reasonable moderation).

Glossary

Critically endangered Facing extremely high risk of extinction in the wild, based on specific criteria (see IUCN, 2001).

Data deficient Appropriate data are lacking to apply the International Union for Conservation of Nature (IUCN) criteria.

Endangered Facing very high risk of extinction in the wild, based on IUCN criteria.

Extinct There is no reasonable doubt that the last individual has died, based on exhaustive surveys at

appropriate times in proper habitat throughout historical range.

Extinct in the wild Although extinct, individuals survive in captivity.

Least concern Not qualifying or close to qualifying for any threat category.

Near-threatened Not currently meeting any of the criteria for the above-mentioned threat categories, but close to qualifying or likely to qualify soon.

Vulnerable Facing a high risk of extinction in the wild, based on IUCN criteria.

Introduction

The concept of a threatened bird is easy to grasp but surprisingly difficult to define. A clear idea of what constitutes a threatened bird requires firm notions of taxonomy, geographical scale, and the degree of peril that qualifies the bird as threatened. This article focuses primarily on the endangerment of species at the global scale, but nationally and locally threatened forms, including subspecies, are also considered. The authors' emphasis on global endangerment reflects the premise that total extinction is a worse outcome than local extirpation, although this premise is not necessarily self-evident (Kareiva, 2011).

The discussion on threatened birds is enlightening simply because of the amount that is known about birds compared with other major taxonomic groups. As such, threatened birds offer a window into the broader topic of the loss of biodiversity. Scientists and conservationists have accumulated a wealth of information about threatened birds. Scientists now know in great detail the status of nearly every bird species and the specific threats they face. Based on their knowledge of threats and experience with management techniques, they have increasingly refined their notions of what conservation actions need to be prioritized (Wilson *et al.*, 2009). Few (if any) other taxonomic groupings permit this level of analysis. Partly for this reason, avian conservation biology has provided conservation biology at large with a wealth of case studies, insights, and technical knowledge.

This article aims to provide an overview of threatened birds around the world. Information and statistics about global patterns of bird endangerment frame the discussion, enabling the identification of the most important threats faced by threatened birds today. A survey of these threats is followed by a review of management techniques and conservation opportunities. Detailed discussion of threats and conservation measures is beyond the scope of this article. Instead, brief summaries of the issues are complemented with specific examples.

Numbers and Trends in the Endangerment of Birds

Taxonomists currently recognize more than 10,000 species of birds in the world, many of which are threatened. Rather than making sense of the global situation on a species-by-species basis, it is helpful to recognize broad trends in bird endangerment. This section discusses some of the most basic questions about global patterns: How many threatened birds are there, and how severe is their plight? Is their status improving or deteriorating? Where do they occur and in which habitats? How does the picture differ when viewed through global versus regional and national lenses? This sort of information allows us to recognize globally important threats to birds and provides the background against which to appreciate specific examples.

Such a discussion requires precise criteria to identify species that are in peril of extinction as well as the empirical data to apply those criteria correctly. In the last 45 years, global species endangerment has been registered principally through the Red Data Book program of the International Union for Conservation of Nature (IUCN), with BirdLife International in charge of the Red List for birds (BirdLife International, 2000, 2011). The IUCN has developed objective criteria to categorize the degree of a species' endangerment based on the severity of its plight, applying thresholds for range and population size and decline designed to reflect the probability of extinction (IUCN, 2001). Hereafter, this article capitalizes terms such as "Endangered" or "Extinct" to refer to particular IUCN Red List categories (IUCN, 2001); the authors use the term "threatened" to refer to imperiled species in general, comprising the ensemble of Critically Endangered (CR), Endangered (EN), and Vulnerable (VU).

Notwithstanding all we know about birds, incomplete data still cause obstacles to their conservation. The species-level taxonomy of birds is unresolved and continues to change. Furthermore, the information required to apply the IUCN's threat categories is sometimes not known. As a result, a few

bird species cannot be assigned a threat level currently, whereas in nearly all others, the threat level is based on estimation, as opposed to precise empirical data. Nevertheless, compared with most taxonomic groups, bird conservation benefits from an extraordinary wealth of information, and threatened birds benefit from an extraordinary degree of conservation effort.

Globally Threatened Birds in 2011: Numbers and Outlook

The IUCN Red List (2011) and the companion publication *Threatened Birds of the World* (BirdLife International, 2000) are the definitive references on global patterns of bird endangerment. The 2011 update to the IUCN Red List recognizes 10,052 species extant after AD 1500. Of these, 132 (1%) species are now Extinct (EX). Of the remaining species, 189 (2% of extant species) are Critically Endangered (CR), 381 (4%) Endangered (EN), and 683 (7%) are Vulnerable (VU), representing 13% of the world's currently extant avifauna. A further 844 species (8%) are considered Near-Threatened (NT), indicating that they may become threatened in the future, whereas almost all remaining species are classified as Least Concern (LC). Insufficient information exists to assess the status of only 62 species (1%), classified as Data Deficient (DD). Thus, 2159 bird species, or 22% of the world's avifauna, are identified as being of global conservation concern.

Across the board, these totals are higher than the equivalent totals from previous assessments (Collar *et al.*, 1994; BirdLife International, 2000). However, using such figures to infer temporal trends in bird endangerment is not straightforward. Most changes in the threat status of bird species reflect taxonomic revisions or newly available population data rather than genuine changes in the status of bird populations. The “splitting” of species-level taxa can cause threatened bird species to appear out of thin air, especially because the populations of the newly split taxa necessarily will be lower than their total population. Similarly, novel information about a species' population may warrant a change in the threat assessment without reflecting any change in the actual status of the species.

One illustration of the temporal trends in bird endangerment comes from the fact that the vast majority of red-listed birds have decreasing populations. This trend arises because the outlook for many bird species continues to deteriorate, but it is partly circular because severe population declines trigger inclusion on the Red List. Only species with irremediably small ranges or populations are listed in absence of an active threat or population decline. Birds like the Lava Gull (*Larus fuliginosus*) VU, with 300–400 pairs maximum, and the Cocos Flycatcher (*Nesotriccus ridgwayi*) VU, found only on an island of less than 25 km², destined to remain forever threatened, and the price of their survival is eternal vigilance.

Another general picture of the deteriorating status of threatened birds derives from the Red List Index, a metric developed by the IUCN to track changes in Red List status due to genuine changes in population status (Butchart *et al.*, 2004). For birds, the Red List Index has consistently shown negative trends since 1988, and the pattern holds across all major geographic regions of the planet when their avifaunas are disaggregated. Unmistakably, birds across the globe are becoming more threatened.

Globally Threatened Birds: Regions, Countries, and Habitats

Most threatened bird species occur in Asia and South America, with comparatively few in Africa. The top 10 countries for numbers of threatened birds are Brazil (122), Indonesia (119), Peru (98), Colombia (94), China (84), India (77), USA (76), Philippines (73), Ecuador (72), and New Zealand (69). USA ranks high on the list largely because of Hawaii and its Pacific territories; otherwise, Asia and South America predominate. Together, the top 10 countries are home to 729 (58%) of the 1253 species of threatened birds in the world.

Large numbers of Endangered and Critically Endangered birds occur on islands – 99 species on the Pacific islands of Oceania (including the Hawaiian archipelago but not the Australian mainland) alone, 50 in Indonesia, 32 on the Caribbean Islands, and 27 in the Philippines. The contemporary situation is but a narrow snapshot of a centuries-old pattern of bird endangerment and extinction on islands (*see* Extinct Birds). In a historical sense, the noteworthy feature of present bird endangerment is the large number of threatened mainland birds, including 165 Endangered and Critically Endangered species just in South America. Ricketts *et al.* (2005) note that the growing roster of Endangered and Critically Endangered species of birds and other taxa on continents portends the movement of the anthropogenic extinction wave from islands to the more species-rich continents (*see* Causes of Endangerment in Birds).

Because most of the world's bird species (76%) live in forests, it should come as no surprise that most threatened birds are forest dwellers – in fact, the figure is precisely 76%. This figure represents a balance between rampant forest destruction across the globe and the fact that the largest tracts of forest, in Amazonia, the Congo basin, and New Guinea, are – despite the destruction visited on them – still too extensive, and the species they contain are too widespread, to have resulted in more than a small number of listings from these areas. Shrublands harbor 27% of threatened bird species, inland wetlands harbor 16%, and grasslands harbor 16%. Marine habitats collectively, including coastal and intertidal areas, are home to 13% of the threatened bird species. The percentages sum to more than 100 because many bird species utilize multiple habitat types in different parts of their range or at different times of year. In the former case, preservation of either habitat may be sufficient to permit the survival of the species; the latter case often requires the conservation of both habitats.

Globally Threatened Birds: Taxonomic Groups

Particular taxonomic groups with high proportions of threatened birds often reflect a group's collective sensitivity to a particular threat, and a survey of threatened bird orders will help to frame the discussion of threats later in this article. Although nearly every extant bird order contains at least one threatened species (exceptions being the loons (Gaviiformes) and mousebirds (Coliiformes)), some orders and families have been particularly hard-hit. Of the 129 extant tubenoses (Procellariiformes), 59 (46%) are threatened. Within the Procellariiformes, the 22 extant species in the albatross family (Diomedidae) include 17 threatened species (77%),

many of them Critically Endangered. Eleven of 18 (61%) penguins (Sphenisciformes) are threatened, as are 97 of 355 (27%) parrots (Psittaciformes), 74 of 291 (25%) game birds (Galliformes), and 58 of 205 (28%) rails and cranes (Gruiformes). The rails also feature heavily among the recently extinct birds, largely due to their evolutionary diversification on islands. To place these percentages in perspective, recall that the overall percentage of threatened birds is “only” 13%.

Regionally Threatened Birds in USA and UK

Patterns of bird endangerment and conservation priorities at regional and global scales are not necessarily identical. Because bird conservation organizations have availed themselves of high levels of interest and funding to thoroughly assess the status of birds in the USA and the UK, these countries provide a lens to understand patterns at the regional scale and to appreciate the plight of declining birds that miss global IUCN criteria for endangerment. In the USA, the American Bird Conservancy and the National Audubon Society have developed the WatchList, classifying the entire avifauna into the threat categories red, yellow, and green (Butcher *et al.*, 2007). Similarly, in the UK, the Royal Society for the Protection of Birds (RSPB) has developed a list of Birds of Conservation Concern, categorizing the avifauna in the categories red, amber, and green (Eaton *et al.*, 2009).

The 2007 WatchList applies criteria based on population size, range size, threats, and population trend to determine the status of US birds (Panjabi *et al.*, 2005). The WatchList gives “red” status to 59 birds of the continental USA (including Alaska) and to an additional 33 from Hawaii. “Yellow” status is accorded to 117 birds of the continental USA. Together, these birds represent about a quarter of the avifauna of the continental USA. Many of these birds are not threatened under global criteria, as they may be relatively common in other parts of the world. For example, the Yellow Rail (*Coturnicops noveboracensis*) is listed as “red” on the WatchList but is placed in the Least Concern category on the Red List. Only 37 birds on the continental USA WatchList (21% of continental species on the WatchList), mostly in the red category, are globally threatened (VU or higher) based on IUCN criteria; many of the remaining birds are NT. Of the 52 birds on the RSPB’s Red List, only 2, the Balearic Shearwater (*Puffinus mauretanicus*) CR and the Aquatic Warbler (*Acrocephalus paludicola*) VU, are globally threatened under IUCN criteria. The remainder is listed based on severe historical declines in the UK without recent recovery or based on more recent declines in UK breeding population, wintering population, or breeding range, since either 1969 or 1984. Twenty-seven of the UK red-listed birds are species of European conservation concern (BirdLife International, 2004). Because IUCN status was a trigger for inclusion on the UK red list, no globally threatened birds were left off, but the Balearic Shearwater’s listing was not triggered by any other criterion. The amber list includes an additional 126 species with declining UK populations (but not severely enough to merit inclusion on the red list), low UK populations, or localized UK distributions. Also included are all remaining species of European conservation concern.

The USA and the UK share critical cultural and economic similarities, and trends in the local endangerment of their birds might not hold everywhere in the world. However, the detail of the WatchList and RSPB’s Birds of conservation concern provides the best available picture of regional trends. Both regional lists designate more birds as threatened than that listed by BirdLife International. This scenario applies particularly to the UK, where birds that are secure at the continental scale may still be threatened regionally. In other cases, different evaluation schemes produce different results. Perhaps regional-scale assessments can afford to list relatively less imperiled species without the risk of muddling global conservation priorities. Most importantly, these lists make it clear that large numbers of globally common birds that miss the IUCN criteria are nevertheless in steep decline.

Extinct Birds

Since AD 1500, at least 132 bird species have gone extinct (EX), and a further four are extinct in the wild (EW). Strikingly, 121 (92%) of these species were confined to islands, mostly in the Pacific, and an additional three were confined to single lakes (BirdLife International, 2011). Moreover, losses since AD 1500 represent only the tip of the iceberg in terms of human-caused extinction of birds. Bird extinctions in the more distant past may be inferred from subfossil data. The spread of Polynesian seafarers across the islands of the Pacific caused between 820 and 1960 bird extinctions, making it one of the largest vertebrate extinction events ever recorded (Steadman, 2006). The number of individual extirpated populations is up to 10 times higher.

Because extinction is only demonstrated by documenting the absence of a species over its entire range, mainland extinctions may be harder to detect than island extinctions. Still, the overwhelming historical preponderance of island extinctions is unambiguous.

Because of the increasing contemporary plight of mainland birds, the few recent mainland extinctions are of heightened interest. Most of these have occurred in eastern North America, where the Labrador Duck (*Camptorhynchus labradorius*), Great Auk (*Pinguinus impennis*), Carolina Parakeet (*Conuropsis carolinensis*), Passenger Pigeon (*Ectopistes migratorius*), and likely the Bachman’s Warbler (*Vermivora bachmanii*) and Eskimo Curlew (*Numenius borealis*) have all vanished. The Ivory-billed Woodpecker (*Campephilus principalis*) is almost certainly gone as well, although controversy lingers about the possibility of its survival (Fitzpatrick *et al.*, 2005; Sibley *et al.*, 2007). Compared with extinct island birds, many of the extinct mainland species ranged over vast areas or occurred in vast numbers, indicating that factors beyond range and population size can put birds at risk for endangerment and eventual extinction. In the cases of the Great Auk, Carolina Parakeet, Passenger Pigeon, Eskimo Curlew, and Ivory-billed Woodpecker, hunting/direct persecution has been implicated as an important factor in their demise. The Bachman’s Warbler may have been extirpated by destruction of its breeding and wintering habitats. Too little is known about the Labrador Duck to make conclusive statements about the causes of its decline.

Causes of Endangerment in Birds

Although some birds are at risk by virtue of their naturally small ranges or populations, the vast majority of threatened birds are imperiled due to the actions of humans. Some 82% are affected by habitat loss and degradation, most often related to agriculture (BirdLife International, 2011). Forty percent are adversely affected by other species in their environment, including invasive exotics or natural competitors that exacerbate additional threats. Hunting and trapping threaten 38% of threatened birds, whereas climate change and severe weather events potentially threaten 33%. In general, small ranges or low populations make birds particularly sensitive to these threats (Note that the percentages sum to more than 100 because most threatened birds are imperiled by multiple factors).

Habitat Loss and Degradation

When habitats change, the birds that lived in them frequently cannot persist in the new landscape. Habitat loss is a major factor in bird endangerment because by the turn of the millennium, at least one-third of the Earth's terrestrial surface had been reshaped by human activities, such as agriculture, ranching, logging, and industrial development (Vitousek *et al.*, 1997). In the humid tropics, where bird diversity reaches its peak, forests were lost or degraded at a rate of approximately 8 million hectares per year during the 1990s (Achard *et al.*, 2002). Deforested land was primarily logged and/or converted to agriculture with major threats, including logging, cattle ranching, soybean farming, and oil palm plantations. The trend is expected to continue. By the year 2050, the Earth's burgeoning population will require up to 1 billion hectares of additional agricultural lands to feed itself (Tilman *et al.*, 2001).

Habitat Destruction

In the simplest cases, birds become imperiled by habitat destruction when their habitat is obliterated over large portions of their range. For example, the Cebu Flowerpecker (*Dicaeum quadricolor*) CR is endemic to the Philippine island of Cebu. Long feared extinct due to the near complete obliteration of forest on the 5088 km² island, it was rediscovered in 1992 in a patch of degraded forest totaling less than 2 km² (Dutson *et al.*, 1993). Because some bird species require much larger territories than others, their range requirements may span several orders of magnitude. On the nearby island of Mindanao, pairs of Philippine Eagles (*Pithecophaga jefferyi*) CR maintain territories of 133 km² on average, including 68 km² of forest (BirdLife International, 2011). Thus, despite the presence of about 9000 km² of forest remaining within its range, this species too is severely threatened due to habitat loss.

A layer of complexity arises when birds use multiple habitats at different times of the year or different regions of a habitat in different years. This is the situation that is faced by all migratory or nomadic bird species. Migratory species can depend on the conservation of multiple disjunct sites comprising multiple habitats. For example, despite attempts to manage the Golden-cheeked Warbler (*Dendroica chrysoparia*)

EN on the shrinking and fragmented oak-juniper woodlands of its small US breeding range, the species also is threatened by the destruction of high-elevation oak woodlands in its Mesoamerican wintering range (Rappole *et al.*, 2003). Similarly, nomadic species may depend on the conservation of vast blocks of contiguous habitat. The Purple-winged Ground-Dove (*Claravis godefrida*) CR is a nomadic species intimately linked to the mast seedings of woody bamboos (Areta *et al.*, 2009). The bamboos occur patchily in space and have inter-mast intervals of approximately 30 years, so the survival of the dove depends on sufficiently extensive areas of forest to ensure that a suitable patch of masting bamboo is generally available, and that the birds can find their way between such patches.

Other examples of this space/time vulnerability include the Thick-billed Parrot (*Rhynchopsitta pachyrhyncha*) EN, Andean Flamingo (*Phoenicopterus andinus*) VU, Resplendent Quetzal (*Pharomachrus mocinno*) NT, and perhaps even the Passenger Pigeon (*E. migratorius*) EX. The parrot shows the same trait as the Purple-winged Ground-Dove because it is dependent on pine seed, a notoriously unpredictable resource. Most, if not all, Thick-billed Parrots are believed to be nomadic, but as their native pine forests in Mexico's Sierra Madre are further fragmented, there is a danger that a cone-crop failure will leave the last populations "stranded" far from food. The flamingo moves between lakes in search of appropriate foraging resources (which shift over time) and is therefore exposed to the possibility that human damage to even a small number of sites may one day leave the species with nowhere to go (BirdLife International, 2011). Postbreeding quetzals make complex short-distance movements to several different areas, so that multiple tracts of forest may be needed to ensure the long-term survival of viable populations of this species (Powell and Bjork, 1994). Bucher (1992) shows how even the Passenger Pigeon was a specialist on seeds produced in masting events whose scale and geographic location varied from year to year.

Habitat Degradation and Fragmentation

Habitat degradation need not entail the wholesale elimination of suitable habitat to pose a threat to species. Pollution, changing land management practices, and even indirect effects of other species on habitat can cause bird populations to decline. The plight of the Junin Grebe (*Podiceps taczanowskii*) CR results from pollution and the management of lake levels. The grebe is entirely confined to Lake Junin, Peru, and declined following the contamination of the lake with mining wastes (Fjeldsa 1984) and the regulation of the lake level by mining companies (BirdLife International, 2011). The Paradise Parrot (*Psephotus pulcherrimus*) EX of Australia disappeared probably due to new burning patterns, livestock grazing, and drought, all of which diminished the availability of the plants that the parrot fed on (Joseph, 1988). Changes in Australian fire regimes also afflict the food supply of the Golden-shouldered Parrot (*Psephotus chrysoterygius*) EN and the habitat of the Noisy Scrub-bird (*Atrichornis clamosus*) VU and Mallee Emu-wren (*Stipiturus mallee*) EN, both of which require areas that have not burned too recently. In the Longleaf Pine savannahs of the southeastern USA, fire suppression is the problem. A lack of fires has permitted the growth of a broadleaf understory, rendering the habitat unsuitable for the Red-cockaded Woodpecker (*Picoides borealis*) VU (Ligon *et al.*, 1986) and

Bachman's Sparrow (*Peucaea aestivalis*) NT. A great variety of subtle changes on the land can cause bird populations to decline.

Species may decline if their habitat becomes fragmented, even if large amounts remain. Local populations in a fragment may die out due to either stochastic processes or Allee effects, and the fragment may not be recolonized if dispersal is poor. This situation has been documented for understory-dwelling insectivorous birds in Amazonian forest fragments (Stouffer and Bierregaard, 1995; Ferraz *et al.*, 2007). Alternatively, fragmentation may open bird populations to pressures arriving from the fragmenting matrix, including arriving nest predators and brood parasites (*see* Natives Threatened by Other Natives). In the midwestern USA, these factors appear to turn forest fragments into population sinks for the Wood Thrush (*Hylocichla mustelina*) LC, a yellow species on the WatchList (Robinson and Wilcove, 1994).

Biotic Threats

Sometimes, despite the existence of appropriate habitat, birds may become threatened as a result of the assemblage of other species present there. The introduction of alien (nonnative) predators, competitors, or diseases can result in precipitous declines of native bird species, especially on islands. In other cases, competition or predation from native species can exacerbate the plight of species that are already declining in the face of other threats. Finally, some species depend on particular native species and run into trouble if these native species decline.

Alien Species

On oceanic islands where mammalian predators of birds and nests were historically absent, their introduction has resulted in massive bird declines and numerous extinctions. Across the world's oceanic islands, greater numbers of mammalian introductions (rats, cats, stoats, etc) correlate with higher rates of extinction of native birds (Blackburn *et al.*, 2004). In a few cases, it has been possible to link these declines to specific predators. Because oceanic avifaunas evolved in the absence of mammalian predators, they are behaviorally and physically adapted in ways that leave them highly vulnerable when continental predators establish within their ranges, through either the direct or indirect agency of humans.

These behavioral adaptations are not degenerative. The Dodo (*Raphus cucullatus*) EX was given its name from the Portuguese slang for "stupid," *doido*. But island animals that are especially tame, or that nest in what to human eyes are ludicrously undefended places, or that have lost the function of their wings are not evolutionary failures. On the contrary, these seemingly disadvantageous attributes are the result of continuing evolutionary pressures. Wings cost energy to carry and maintain; and in the absence of predators, they offer no return on the investment to such energy. Shyness costs its possessors dearly if less shy creatures have more time to exploit whatever resource is at stake. Nesting in inaccessible places is needlessly expensive if there is no risk in nesting on the ground in the open. Moreover, the relatively stable conditions on tropical islands tend to promote marked K-selected

traits (e.g., slow reproductive rates). The factors that render island birds vulnerable to aggressive, fast-breeding, continental animals may have been favored by eons of narrower, often intraspecific competition.

Island birds have been, and continue to be, massively impacted by rats (Moors *et al.*, 1992): Magenta Petrel (*Pterodroma magentae*) CR, Tuamotu Sandpiper (*Prosobonia cancellata*) EN, Polynesian Ground-dove (*Gallicolumba erythroptera*) CR, Seychelles Paradise-flycatcher (*Terpsiphone corvina*) CR, and Rarotonga Monarch (*Pomarea dimidiata*) EN are a few of the birds whose declines are directly linked to the invasion of their islands by rats. Species on larger islands face introduced predator assemblages that include cats, and the large island size makes predator control or eradication particularly difficult. The New Caledonian Rail (*Gallirallus lafresnayus*) CR (perhaps EX), Cuba's Zapata Rail (*Cyanolimnas cerverai*) CR, the Samoan Moorhen (*Gallinula pacifica*) CR (perhaps EX), and virtually the entire surviving endemic avifauna of Hawaii (notably the honeycreepers, Drepanididae) are good examples of this difficulty. Mongooses, which were often released to devour rats or control snakes, are major threats to species, such as Hawaiian Duck (*Anas wyvilliana*) EN and St. Lucia's Semper's Warbler (*Leucopoea semperi*) CR (perhaps EX). Introduced diseases may also cause disaster among local bird populations. Accidentally introduced mosquitoes carrying avian malaria and pox devastated Hawaii's land birds and continue to pose a serious problem, which may worsen with climate change (van Riper III *et al.*, 1986; BirdLife International, 2011). Numerous other diseases, including avian botulism, West Nile virus, and avian cholera are just a few diseases that have caused worrisome declines in threatened birds (Butchart *et al.*, 2010). Mammals are not the only alien predators to cause harm. In Guam, most of the island's native birds were extirpated by the accidentally introduced brown tree snake (*Boiga irregularis*) (Savidge, 1987).

In other cases, introduced competitors (rather than predators) cause problems. New Zealand's Kaka (*Nestor meridionalis*) EN and Yellowhead (*Mohoua ochrocephala*) EN face enormous difficulties now as the introduced wasps compete with them for honeydew, an important foodstuff (breeding success in the Kaka correlates with honeydew intake in the previous autumn). The White-headed Duck (*Oxyura leucocephala*) EN faces long-term extinction through hybridization with its New World counterpart, the Ruddy Duck (*Oxyura jamaicensis*) LC, which is spreading through the White-headed Duck's range from an original feral population in Britain (BirdLife International, 2011).

Natives Threatened by Other Natives

Sometimes threats come not from introduced exotics but from natives expanding their ranges, often owing to human modifications of habitat. The spread of cowbirds (*Molothrus* spp.) in the USA and the Caribbean islands is particularly worrying. Birds, such as Kirtland's Warbler (*Dendroica kirtlandii*) NT and Black-capped Vireo (*Vireo atricapillus*) VU, need constant effort programs to reduce cowbird brood parasitism to tolerable levels. Similarly the spread of the Pearly-eyed Thrasher (*Margarops fuscatus*) LC, a nest-hole competitor, through the Caribbean islands has been viewed with alarm by the Puerto Rican Amazon (*Amazona vittata*) CR recovery teams.

Researchers classify such species as Conservation Dependent in recognition of the possibility that they will need perpetual care (Scott *et al.*, 2005).

In the face of declines due to other factors, even normal pressures from native species may become problematic. On New Zealand's Chatham Islands, nest predation by the native Weka (*Gallirallus australis*) LC has contributed to the decline in numbers of Chatham Oystercatcher (*Haematopus chathamensis*) EN, an endemic species already threatened by the introduced mammalian predators. On Bermuda, White-tailed Tropicbirds (*Phaethon lepturus*) LC outcompete Bermuda Petrels (*Pterodroma cahow*) EN for nests and must be controlled in the vicinity of petrel colonies.

A separate class of cases involves birds that depend on particular native species. When these native species decline, it spells trouble for the birds that depend on them. For example, the Cuban Kite (*Chondrohierax wilsonii*) CR is threatened by habitat loss and persecution, but the harvesting of tree snails, its major foodstuff, has exacerbated its problems (BirdLife Internaional, 2011). Shorebirds that utilize Delaware Bay, USA as a spring stopover site have been hard-hit by the harvesting of Horseshoe Crabs there for fish bait. Most of the world's Semipalmated Sandpipers (*Calidris semipalmatus*) LC and most of the eastern North American population of Red Knots (*Calidris canutus*) LC feed on the eggs of spawning Horseshoe Crabs, putting on fat reserves that enable them to continue northward to their Arctic breeding grounds. Both species have shown serious declines as a result of the Horseshoe Crab harvest, and both are yellow species on the WatchList.

Complicated pathways involving multiple species and indirect effects can also degrade bird habitat. The decline of Northern Wheatears (*Oenanthe oenanthe*) LC in the Netherlands apparently results from grass and shrub encroachment following the decline of rabbits in their dune habitat (van Oosten, 2010). The extirpation of apex predators from huge portions of the planet's terrestrial surface is likely responsible for a suite of underappreciated habitat changes and threats, including mesopredator release (Estes *et al.*, 2011), which has been tied to declines of North American songbirds (Wilcove, 1985; Soulé *et al.*, 1988).

Hunting, Trapping, and Poisoning

Some birds are threatened due to capture and/or mortality directly caused by humans. In many cases, the killing of birds is deliberate (whether rational or not), but in other cases it is incidental to other activities. The former cases include hunting for sustenance and trapping for the pet trade; both phenomena have produced major declines in some birds, and overharvesting contributed to approximately one-third of extinctions since 1500 (Butchart *et al.*, 2010). Avian families with especially high rates of endangerment often suffer from particular threats in combination, with habitat loss or alien species compounded by unsustainable harvesting (Collar *et al.*, 1997). For example, the parrots (Psittacidae) and curassows and guans (Cracidae) have declined due to habitat loss, but the parrots also experience intensive trapping for the pet trade, and the Cracids are intensively exploited for food. Trapping has contributed to the endangerment or extinction

of approximately one-quarter of the world's parrots. Among the Cracidae, the curassows (genera *Crax*, *Mitu*, *Nothocrax*, and *Pauxi*) have been especially hard-hit by hunting. Hunting for food has contributed to the extinction in the wild of the Alagoas Curassow (*Mitu mitu*) and to the endangerment of 6 of the 13 remaining species, with a seventh species Near-Threatened (BirdLife Internaional, 2011). Historically, extinctions have resulted from the overzealous persecution of threatened species by specimen collectors. The curse of economic value combined with restriction to a beleaguered habitat type confers a strong likelihood of endangerment.

In addition to hunting and trapping for sustenance and sale, some birds are persecuted accidentally. Accidental bycatch in longline fisheries pressures all 22 of the world's albatross species (Diomedidae), 17 of which are globally threatened. Birds attempt to take floating frozen bait, become hooked, and eventually drown. Spoon-billed Sandpipers (*Eurynorhynchus pygmeus*) CR wintering in Southern Asia have been trapped by hunters targeting larger species (Bird *et al.*, 2010). The Marbled Teal (*Marmaronetta angustirostris*) VU is primarily threatened by habitat loss but is also vulnerable to accidental capture in fishing nets (BirdLife Internaional, 2011). Vulture (genus *Gyps*) populations in South Asia have plummeted due to inadvertent poisoning by the veterinary drug diclofenac, with three of five of India's vulture species Critically Endangered for this reason (Shultz *et al.*, 2004). In Africa, vultures like the Lappet-faced Vulture (*Torgos tracheliotos*) VU are inadvertently poisoned by strychnine bait set for predator control (Ogada and Keesing, 2010). Other large raptor species, including the California Condor (*Gymnogyps californianus*) CR and the Spanish Imperial Eagle (*Aquila adalberti*) VU, are susceptible to inadvertent poisoning by the ingestion of lead shot. Many raptors are shot due to the belief, generally incorrect, that they pose a threat to poultry or livestock. For example, the Cuban Kite (*C. wilsonii*) CR feeds on tree snails, but it is still shot as a perceived threat to poultry (BirdLife Internaional, 2011).

Small Ranges and Large Aggregations

When birds occur in small ranges, localized disturbances can have catastrophic effects on the entire population. The entire population of Montserrat Oriole (*Icterus oberi*) CR lives essentially in the shadow of an active volcano on islands where hurricanes are likely. As noted previously, a strikingly high proportion of threatened and extinct birds occur on islands, where a small amount of habitat destruction might completely obliterate their habitat.

Similarly, species that concentrate in a small area for even part of their life cycle may be abnormally exposed to danger. For example, although they forage at sea, the entire world population of Ascension Frigatebird (*Fregata aquila*) VU breeds on a single stack smaller than a municipal parking lot. The Semipalmated Sandpiper and Red Knot depend on specific staging grounds (i.e., the Delaware Bay) on their northbound migration (see Biotic Threats). Even birds that are briefly drawn to individual fruiting trees are liable to suffer: In October 1997, as many as 40 Visayan Hornbills (*Aceros waldeni*) EN on a single tree were shot over the course of a single day.

Climate Change

Global climate change may already be affecting bird populations across the globe. In the Netherlands, declines in the breeding population of pied flycatchers have been tied to the earlier emergence of leaves in the spring. The flycatchers depend on abundant caterpillars to feed their young. In apparent response to warmer temperatures, the caterpillars have been emerging earlier. Although the flycatchers have been laying their eggs earlier in the spring, they have not been able to do so early enough to synchronize feeding their offspring with the peak numbers of caterpillars (Both *et al.*, 2006). In places as disparate as California and Peru, montane species are ascending to higher elevations (Tingley *et al.*, 2009; Forero-Medina *et al.*, 2011).

It is difficult, however, to definitively implicate anthropogenic climate change in the contemporary imperilment of threatened birds. For the most part, global climate change is a specter looming on the horizon. Particularly vulnerable bird groups include those that depend on pack ice (e.g., Ivory Gull (*Pagophila eburnea*) NT) or occur mostly at the highest elevations of mountain ranges (e.g., Bicknell's Thrush (*Catharus bicknelli*) VU), are vulnerable to emerging or introduced infectious diseases (e.g., the native land birds of Hawaii), or any bird restricted to a specific habitat type in a narrow geographic area. There are many examples of this latter type. For example, the Hooded Grebe (*Podiceps gallardoi*) EN of southern Argentina and Chile occurs only in a few alkaline lakes and was adversely affected by a single year of drought in 2006 (BirdLife International, 2011). The consequences of long-term climatic shifts for a bird such as this could be catastrophic.

Approaches to the Conservation of Threatened Birds

When it is possible to identify specific threats to threatened birds, it is usually possible to identify potential solutions. The implementation of these solutions, however, is often technically difficult, politically difficult, or costly. To present a portfolio of solutions, a brief discussion of ground rules for establishing priorities is warranted.

Goals and Priorities

For many conservationists, the notion of endangered species suggests that preventing extinctions should be a high priority – even the top priority – but valid, alternative goals exist. The preservation of ecosystem services, the preservation of intact ecosystems, the preservation of migration as a phenomenon of abundance, and the preservation of keystone or umbrella species – none of these goals overlaps perfectly with the prevention of extinctions. Even if the preservation of extinctions is taken as the goal, priorities may be required to determine which extinctions to focus on preventing. Should global extinctions always take precedence over local extirpations? Species over subspecies? Monotypic genera and families over species with close relatives? Need some species be triaged? Which species are sufficiently common that they do not require attention?

It is beyond the scope of this article to answer these questions, but it is worth noting that different governments and organizations have answered them in different ways. For example, the US Endangered Species Act provides regulatory protection and management resources to subspecies and vertebrate populations, in addition to full species. Under the US Endangered Species Act, the decision to designate a species, subspecies, or population as endangered is supposed to be made solely on scientific grounds, a laudable principle. In reality, however, political, economic, and other nonbiological considerations sometimes muddle the designation process (Wilcove, 2010). Political and other considerations certainly affect the subsequent efforts to save the species, subspecies, or population in question.

Problems of Definition: Scale

Because policy and legislation affecting threatened species is often formulated at the national level, the conservation of globally threatened species does not always take precedence over the conservation of regionally threatened but globally widespread species. Species may be declared nationally endangered without being globally threatened. For example, the Spotted Owl (*Strix occidentalis*) NT is an endangered species under US law, but it still misses the IUCN criteria due to its populations in Mexico. In other cases, no trend toward global endangerment is present at all. The tiny US population of Snail Kite (*Rostrhamus sociabilis*) LC is endangered in that country despite robust populations in the tropical Americas. Although the Snail Kite is not globally threatened, US endangered species legislation legitimately devotes resources to its conservation.

Managing Priorities

The bewildering array of decisions confronting conservationists has resulted in attempts to systematically identify strategies that satisfy multiple priorities simultaneously. This is especially the case for habitat conservation (*see* International Cooperation and Legislation). It stands to reason that in some cases the preservation of a threatened habitat can benefit numerous threatened bird species simultaneously. For example, it is possible to delimit regions that total less than 1.4% of the Earth's terrestrial surface, but contain more than 28% of the world's bird species (Myers *et al.*, 2000). Presumably, targeted conservation of such "biodiversity hotspots" could provide the maximum benefit for the limited resources available.

Similarly, BirdLife International identified Endemic Bird Areas (EBAs), regions with significant numbers of endemic birds (Stattersfield *et al.*, 1998). The importance of EBAs lies in the fact that if an EBA is entirely destroyed, its endemic avifauna will face global extinction. At the same time, BirdLife has set out to identify Important Bird Areas (IBAs), places that hold at least one globally threatened species, several rare species, or major concentrations of common species. IBAs identify the priority localities for conservation both within and outside hotspots and EBAs.

Site and Habitat Conservation and Management

In response to habitat loss and degradation, the commonest conservation approach is to protect and manage landscapes

for the benefit of the conservation targets. The key tool for conservation is typically the protected area. Management may occur on protected areas (where even the decision to leave the landscape as undisturbed as possible constitutes a management decision of sorts) or outside of protected areas, for example in agricultural or urban landscapes. Typically, preservation is the primary response in cases of habitat loss (e.g., conversion of tropical forests to oil palm plantations), whereas management is important in cases of habitat degradation (e.g., grasslands overgrazed by livestock). These strategies often compliment and overlap one another, as in the case of prescribed burns within state parks to manage habitat for the Florida Scrub-Jay (*Aphelocoma coerulescens*) VU. But if a region is to meet a specified agricultural production target, there may be a difficult tradeoff between employing low-impact farming over a large area and high-impact farming concentrated into a smaller area but accompanied by habitat preservation (Phalan *et al.*, 2011).

International Cooperation and Legislation

Bird conservation extends across international boundaries in three principal ways. First, the birds themselves physically cross the boundaries. The conservation of migratory species frequently depends on the participation of multiple nations and multiple polities within nations along the migratory route. A Swainson's Thrush (*Catharus ustulatus*), for example, flying from its wintering grounds in western Brazil to its breeding grounds in southern Manitoba, Canada, may pass through (or over) 10 different countries and more than 40 states, provinces, departments, and other major subnational jurisdictions (Wilcove, 2008). Second, certain threats such as international trade in threatened birds or global climate change are international in scope and must be dealt with at the international level. Third, some nations may require international assistance to implement conservation policies domestically.

Although trade is not a strong factor in the endangerment of birds in general, it is important for a few groups of species, most notably the parrots. The major international instrument for the control of trade is the Washington Convention, universally known as the Convention on International Trade in Endangered Species (CITES), which has been in operation since the 1970s. Animals and plants may be registered in three ways: on Appendix I, which essentially prohibits all movement of the species in question; on Appendix II, which prohibits all commercial trade except under license; and on Appendix III, which allows a particular nation to prohibit trade across its borders irrespective of a species' status elsewhere.

Because of the immense volume of traffic in parrots, and the problem of identification in so diverse a family (approximately 350 species), all but three species were placed on Appendix II in 1981. This move had the intention, if not the effect, of giving protection to the more threatened parrots – naturally their rarity increased their desirability among bird fanciers – which, if listed alone on the Appendix, could easily have been traded indiscriminately under other names without customs officials necessarily being able to identify them. Appendix II species have quotas set by

exporting countries, in theory based on data that show the exploitation to be sustainable. Where the evidence suggests that it is not, movement to Appendix I is supposed to bestow immunity.

Curiously – but as a measure of the power that some trade interests can exert – listing on Appendix I can actually stimulate trade not only while the species is still at the proposal stage for upgrading but also following listing, on the basis of its enhanced rarity value. This happened to the Hyacinth Macaw (*Anodorhynchus hyacinthinus*) EN, whose rarity in the wild today is primarily a consequence of a trapping blitz in the 1980s. In general, CITES trade controls have some effect and allow for very useful monitoring of changes in trading fashions over time. However, for truly prized species such as Lear's Macaw (*Anodorhynchus leari*) EN and Spix's Macaw (*Cyanopsitta spixii*) CR, both from Brazil, there is little that any control system can do to eliminate smuggling: The financial inducements are simply too strong. The same tends to be true in Indonesia for exquisite songsters, such as the Straw-headed Bulbul (*Pycnonotus zeylanicus*) VU and good lookers, such as the Bali Starling (*Leucopsar rothschildi*) CR.

Other important international instruments for threatened birds are the Ramsar Convention (for important wetlands), Bonn Convention (for migratory species), and Berne Convention (for European species). The Convention on Biological Diversity ought to be a key aspect of threatened species conservation across the planet, but considerable effort by non-governmental organizations is needed to ensure the inclusion of global priorities in the national conservation strategies that each party to the convention is obliged to produce and implement.

The United Nations' Reducing Emissions from Deforestation and Forest Degradation program (REDD and REDD +, the latter encompassing managed forests) has the potential to provide an international mechanism for the conservation and sustainable management of large amounts of forests and other carbon-rich ecosystems, while also potentially slowing the onset of global climate change, although there remain many questions about how such a program will be implemented and monitored.

Management Techniques for “Critically Endangered” Birds

Habitat Restoration

Major conservation projects almost invariably involve some habitat restoration work. However, for species at the brink of extinction through habitat loss, the emphasis falls more directly on the rapid replanting of food plants and land areas. Lear's Macaw appears to be constrained by the availability of licuri palms (*Syagrus coronata*), many stands of which show no sign of regeneration owing to cattle grazing: Programs have long been planned to establish many new groves within the species' range. The Cebu Flowerpecker survives in a few areas of heavily degraded forest that total less than 10 km². Efforts are under way to reforest adjacent areas within the next 30 years. There is now an emerging discipline of restoration ecology, and it is likely that a great deal of conservation energy in the twenty-first century will be

channeled into reconfiguring habitats that were ruined during the twentieth century.

Control and/or Restriction of Aliens and Natives

Eradication of alien predators and pests from islands has been pioneered in New Zealand, where several small offshore islands have been rid of various mammals both to preserve resident breeding species and to translocate stricken native species from the main islands (Clout and Craig, 1995). This painstakingly systematic restoration of islands – mainly involving the elimination of cats, rats, and mustelids – has been essential to the survival of birds, such as the Black Petrel (*Procellaria parkinsoni*) VU and Kakapo (*Strigops habroptilus*) CR, and the expertise generated is now being exported to other islands in the Pacific and Indian Oceans.

Researchers on Mauritius recently discovered the reason why the native Pink Pigeon (*Nesoenas mayeri*) EN and Mauritius Fody (*Foudia rubra*) EN have managed to persist in the face of rat predation. These birds now nest almost exclusively in a grove of exotic *Cryptomeria japonica*, whose bark produces a sticky gum and whose leaves consist of spiny needles, both of which discourage rats from getting at nests. Curiously, then, in rare cases, it appears that exotic vegetation can help rather than hinder native species in their struggle against exotic predators; in this instance, the planting of more *Cryptomeria* is clearly called for.

Captive Breeding

Captive breeding has several major drawbacks because even when the breeding program is successful, problems of imprinting, migratory patterns, and techniques for survival in the wild plague reintroduction attempts. An additional serious problem is the possibility of disease transmission to wild birds from captive stock (Snyder *et al.*, 1996). Nevertheless, captive breeding has achieved several outstanding successes. The Northern Bald Ibis (*Geronticus eremita*) CR and California Condor both flourish in captivity while efforts to improve environmental conditions in the wild continue. The Lord Howe Woodhen (*Gallirallus sylvestris*) EN and Guam Rail (*Gallirallus owstoni*) EW, members of a notoriously vulnerable family (because so many rails reached islands in the past and proceeded to lose the power of flight), only persist thanks to *ex situ* regimes. The Socorro Dove (*Zenaidura macroura*) EW survives only because a few Californian bird fanciers took and bred specimens at a time before its native island was overrun by exotic predators. In 1998 the Bali Starling was within eight individuals of becoming extinct in the wild owing to relentless poaching for trade, but zoos throughout the world have bred the species such that many hundreds and perhaps thousands survive for possible reintroduction when poaching has finally been brought under control.

There is also a role for veterinarians in intensive *in situ* management programs, through their expertise in providing appropriate advice on toxicity of nest box materials, control of nest parasites, composition and secure provision of supplementary foods, disease screening, and minimization of cross-fostering and translocation exercises.

Reintroduction and Translocation

The extirpation of a species at a discrete site may have been caused by a short-term or remediable factor, so that restocking with individuals from elsewhere can be undertaken. Such an endeavor requires careful planning (Black, 1991). A series of feasibility assessments should determine the site's continuing ecological suitability (the original constraining factors must no longer operate); the threats it faces; the availability of appropriate stock; the socioeconomic implications; and local, national, and international awareness needs. The birds must be in optimal condition; and if captive-bred, they should have been reared in disease-free conditions and in such a way as to be behaviorally and genetically fit for independence in nature. Monitoring of the project is crucial, and it should be documented for circulation to other biologists contemplating such efforts.

Bird species that have benefited from well-designed reintroduction programs include the Peregrine Falcon (*Falco peregrinus*) LC and Chatham Islands Snipe (*Coenocorypha pusilla*) VU. Those that were not included are Cheer Pheasant (*Catreus wallichii*) VU in Margalla Hills, Pakistan (fox predation) and Thick-billed Parrots in the USA (the wild-caught birds flew back to Mexico; the captive-bred ones did not move very far and were unusually vulnerable to predation by raptors).

Translocation to previously unoccupied sites has become a greatly valued technique, if only as a temporary measure while efforts are concentrated on habitat restoration or predator eradication at the native site. Beneficiaries of this approach include Tongan Megapode (*Megapodius pritchardii*) EN, Vini lorikeets, Kakapo, Seychelles Magpie-Robin (*Copsychus sechellarum*) EN, and Seychelles Warbler (*Acrocephalus sechellensis*) VU. The work done in preparation for the Seychelles Warbler translocations showed that target islands had many times the insect abundance of the host island, Cousin. This was clearly related to the absence of predation pressure on the insect fauna, and – unsurprisingly but still very strikingly – when birds were released onto the target islands, they began breeding almost immediately and very rapidly expanded their numbers. On Cousin Island, the birds had been so packed that they bred only very slowly, with one offspring tending to stay on territory and help at the nest, waiting for a parent to die (Komdeur *et al.*, 1997). This observation underscores the value of the food resource base in managing threatened birds and leads to the next point.

Supplementary Feeding

The value of increasing food availability for species whose populations need rapid growth seems to have been perceived only relatively recently, perhaps beginning with work on Peregrine Falcons (see Temple, 1978). The technique has been adopted for threatened birds on Mauritius, principally with the Mauritius Kestrel (*Falco punctatus*) VU, for which extra food clearly enhanced reproductive output (Jones *et al.*, 1995). New Zealand workers have found the same with the Kakapo: Normally the species breeds only in response to major mast-ing events, which may occur once every 5 years, but with dietary supplements, it appears to be capable of breeding every year. On Hokkaido, Red-crowned Cranes (*Grus japonensis*) EN have recovered from near extirpation through a combination

of better protection and extensive food provision. Clearly, as a relatively short-term measure, supplementary feeding can be crucial in producing an unnaturally rapid reproductive output, a very desirable effect in critically low populations where the genetic value of every individual needs to be maximized.

Nest-Site Provision or Enhancement

Where nest sites are limiting (often the case with hole-nesting species), the provision of nest boxes or the enhancement of natural cavities may be appropriate. Puerto Rican Amazons ignored the former but benefited from the latter. Mauritius Kestrels greatly benefited from the creation of nesting ledges. The provision of grilles at burrow entrances has helped prevent White-tailed Tropicbirds from appropriating Bermuda Petrel burrows (see *Natives Threatened by Other Natives*).

Cross-Fostering and Cross-Breeding

Many large raptors and most cranes lay two eggs but normally rear only one young, so biologists attempting to increase productivity of threatened forms of such birds have long sought to make use of the expendable second eggs by taking them for hatching and captive breeding. The most famous instance of cross-fostering involved the Black Robin (*Petroica traversi*) EN, whose population fell to five individuals in 1980 but recovered by placing some eggs in the nests of Tomtits (*Petroica macrocephala*). In the case of the Whooping Crane (*Grus americana*) EN, an attempt was made to establish a second population by placing such eggs in the nests of Sandhill Cranes (*Grus canadensis*) LC, but this did not result in a breeding population, possibly as a result of imprinting.

Cross-breeding with another subspecies was regarded as the last hope of the Dusky Seaside Sparrow (*Ammospiza maritima nigrescens*), but the last stock died out before the endeavor could succeed. However, it has been used on the endemic Norfolk Island race *undulata* of the Southern Boobook (*Ninox novaeseelandiae*), which by 1986 had been reduced to a single female. After nest boxes were erected to overcome an immediate shortage in nesting sites, two male nominate male boobooks were introduced to the island; one of them paired with the female and in due course produced a string of hybrid offspring. The taxonomic (and legal) implications of this technique pose complexities, but it clearly represents a means of preserving genetic diversity.

Caveats

Although the ability of conservation professionals to rescue threatened birds via hands-on techniques, such as translocation, food supplementation, and cross-fostering is truly impressive, it is emphasized that the use of such techniques is feasible for only a small number of the world's threatened birds, principally those species residing in wealthier countries. The future for most of the world's threatened birds will hinge on whether or not their remaining habitats can be protected and properly managed.

Glossary

Chordate A member of the group Chordata. The Chordata includes the most recent common ancestor of tunicates and cephalochordates and all of that ancestor's descendants. Tunicates, lancelets, hag-fishes, and vertebrates are all chordates.

Ectoderm An embryonic tissue that provides the future outside layer of the animal.

Ectothermy A method of body temperature control in which the animal utilizes external sources for gaining and giving up heat, thus achieving temperature control without affecting metabolic rate.

Endothermy A method of body temperature control in which the animal modifies its metabolic rate to achieve the desired body temperature.

Neural crest An embryonic tissue intermediate between neurectoderm and ectoderm, with cells migrating widely to their final destination. This tissue gives rise to anterior

skeletal elements, many portions of the future head and pharynx, and all pigment cells. Sometimes also referred to as mesectoderm.

Neurectoderm An embryonic tissue that gives rise to the central tube of the nervous system.

Notochord A stiff, flexible, longitudinal rod running along the middorsal portion of the chordate body. It is situated dorsal to the coelom and ventral to the central tube of the nervous system.

Pharynx The anterior portion of the alimentary canal, characterized by lateral buds that provide skeletal support for the gill region.

Tuberculum interglenoideum An anterior projection of the first (cervical) vertebra in salamanders. The tuberculum interglenoideum bears articular facets that insert into the foramen magnum of the skull and provide additional articulation points between the skull and the vertebral column.

Introduction

The vertebrates include most of the major groups of animals that humans encounter and interact with on Earth, and in common parlance, the term “vertebrate” is often equivalent to “animal.” Vertebrates include all the fishes, amphibians, reptiles, birds, and mammals; they are found on every major landmass and in all of the world's oceans and major seas. The fossil record of the group is excellent and extends back to the late Cambrian period of the early Paleozoic, more than 500 million years ago. The vertebrates are members of a nested series of more inclusive groups, extending all the way down the tree of life to a common ancestor they share with bacteria, the most primitive life forms known. In order to properly understand the vertebrates, it is necessary not only to briefly discuss the characteristic features unique to the group but also to evaluate the features they share with their closest living relatives, the hagfishes, lancelets, and tunicates. These organisms plus vertebrates constitute the group Chordata. In the pages that follow, we summarize some generalized characteristics of chordates and vertebrates, examine the early history of these groups as it is revealed from the study of the fossil record, and provide explicit definitions and diagnoses for all of the major chordate groups.

General Vertebrate Characteristics

The diversity among vertebrate groups makes it possible to utilize functional analyses and paleontological data to reconstruct a phylogenetic sequence of vertebrates and to place the currently

surviving (extant) vertebrate groups into a historical sequence. This sequence permits the development of explanatory schemes for some conditions observed in humans. Consequently, the study of the comparative morphology and physiology of vertebrates has proved important for the understanding of the human condition. These studies in turn led to the development of curricular variants for students training themselves for careers in human medicine. Examples are approaches to applied physiology and morphology of the precursors' conditions. Such instructional variants may be presented as the sequential development of the history of a topic such as gas exchange, digestion, or embryology. Alternatively, the study may involve a series of steps, each explaining the condition in one of the subgroups of animals representing putative precursors for the vertebrate condition (i.e., basal chordates or echinoderms), or historical stages in the development of groups of vertebrates (i.e., fishes, reptiles, and mammals).

Although a few arthropods and mollusks achieve large, indeed giant, sizes, most of the largest species, whether terrestrial, aquatic, or aerial, are vertebrates, and this latter group includes the largest animals known. However, some vertebrates are small, almost tiny, and this poses interesting questions of how they perform the basic functions of reproduction, locomotion, respiration, food processing, and waste discharge. Vertebrate size reduction involves two strategies: (1) maintenance of the adult pattern at a reduced body size and (2) the acquisition of metamorphosis, meaning that the life processes, and the structures that facilitate them, change markedly at one or more stages and sizes of development.

Vertebrates may be visualized as elongate, tubular creatures possessed of a central tubule, this being a gut or alimentary

canal. The anterior end of the gut forms a mouth and buccal structures, whereas the posterior end is modified for the storage and ultimate elimination of waste. The central tubule is placed in a lined cavity, the coelom, that also houses various diverticulae of the gut that support aspects of such visceral functions as gas exchange (i.e., gills and lungs, heart, and vessels), digestion (pancreas and liver), fluid balance (kidneys), and reproduction (gonads). The entire animal is coated by a multilayered epidermis that protects the internal tissues from mechanical stresses and can serve as a physiological barrier. The space between coelom and epidermal layer is occupied by the somatic musculoskeletal system that facilitates locomotion and supports and maintains the shape of the coelom and hence of the entire animal.

The musculoskeletal system involves the cartilages and bones of the internal skeleton and the striated somatic musculature. Externally, the system underlies the epidermis, this portion forming a dermis having skeletogenic properties. Two additional median and tubular structures complete this architectural scheme. The first tube, the notochord, lies just dorsal to the gut and is filled with vacuolated cells, their turgor pressure turning the notochord into a stiffened skeletal rod. The second, still more dorsal, tube consists of neuronal cells that involve sensory function and transmission of signals to the musculature.

The entire animal may have various appendages such as fins or limbs, each having characteristic internal skeletal supports and motile capacity developed by the contraction of the attaching striated musculature, which is subdivided into myotomes, paired blocks that parallel the notochord. The notochord provides a capacity for resisting longitudinal stresses, while the appendages involve support of the animal above the substrate and the transmission of laterally directed force patterns.

Whereas this general pattern seems to characterize vertebrate structure, the group shows major curiosities. The various groups of nonvertebrate creatures can generally be diagnosed by a relatively few characteristics. In contrast, there are no fewer than 25 new characteristics shared by vertebrates (Table 1). These involve multiple and major physiological systems, for instance the multiple senses, the head skeleton, the vertebral column, and the digestive system. This clear diversity of vertebrate specializations has long raised questions about the adaptive reasons to explain why these comparable characteristics are modified in vertebrates and why and how a multiplicity of such characteristics might be associated and consequently subject to possibly simultaneous selection. Actually, the answer to this conundrum has been available for some 30 years. Rather than looking at the functions of the many "vertebrate characteristics," namely, aspects seen in the adult condition, it is more informative to base comparisons on the stages of vertebrate embryology or development. The traditional rules that posited firm conditions, such as that the ectoderm formed all the epidermis and the mesoderm all of the striated musculature, soon broke down. In particular, the neural crest, an embryonic tissue intermediate between the ectoderm and the neurectoderm, proved to be the source of many diverse tissues. Similarly, the neurogenic epidermal placodes formed a set of embryonic tissues that provided a source for many shared vertebrate characteristics (Table 1).

Table 1 Derived characters of vertebrata and their embryonic origin^a

<i>Vertebrate characters</i>	<i>Embryonic origin</i>
Nervous system	
Sensory nerves with ganglia, cranial	NC, P
Sensory nerves with ganglia, trunk	NC
Peripheral motor ganglia	NC
Second- and higher-order motor neurons	NC
Forebrain	NC?
Chromatophores	NC

Anterior neurocranium and sensory capsules	NC
Cephalic armor and derivatives	NC
Armor of trunk	NC??, ME?

^aM, mesoderm; ME, mesoderm, epimere; MH, mesoderm, hypomere; NC, neural crest; NC?, intermediate between neurectoderm and neural crest; P, placodes; (P), placodes provide lens and peripheral component, but not sensory tissues. Origin of the various trunk armors is uncertain.

Source: Modified from Gans C (1993) Evolutionary origin of the vertebrate skull. In: Hanken J and Hall BK (eds.) *The Skull: Patterns of Structural and Systematic Diversity*, pp. 1–35. Chicago: Univ. of Chicago Press.

The most interesting aspect was the discovery that many otherwise indistinguishable adult tissues could be derived from different embryonic sources, depending on their position in the embryo. Thus cephalic striated muscle has a histological pattern equivalent to that of the striated muscle of the trunk but is of neural crest rather than mesodermal origin. Similarly, the bones of the skull are derived from neural crest and the more posterior and serially equivalent vertebral bones are of (sclerodermal) mesodermal origin.

Consequently, the vertebrate characteristics either are derived from neural crest of neurogenic epidermal placodes or are induced by these tissues. In contrast to searching for 25 functional issues, the developmental approach makes it possible to recognize two or three associated aspects and note that these provided the cause of the vertebrate condition.

Early Chordate and Vertebrate History

Vertebrates are members of a more inclusive group of animals, the chordates. The history of both chordates and vertebrates

extends back into the Cambrian period in the early Paleozoic. Although the fossil record of early chordates is generally quite poor, several fossil localities have produced fossils that are likely to represent the remains of early chordate animals. Controversy over the interpretation of anatomical features of these animals is in part due to the fact that the important characteristics by which we recognize chordates are soft anatomical features that are not easily fossilized. Exquisite preservation of soft-bodied organisms in the Burgess Shale in Canada (middle Cambrian, approximately 530 million years ago) resulted in the discovery of several specimens of a chordate-like animal named *Pikaia gracilans*. These important fossils appear to display major chordate structural features, including myotomes (segmented muscle blocks) and a stiff, longitudinal rod running along the middorsal portion of the body, the notochord. Some controversy regarding the precise phylogenetic position of *Pikaia* persists due to a lack of adequate description of these fossils in the primary literature. Recent discoveries in early Cambrian deposits in China stimulated renewed interest in the origin and diversification of chordates. *Yunnanozoon lividum* was described as an early representative of the cephalochordates (Chen et al., 1995; Chen and Li, 1997), and *Haikouella lanceolata* was recently identified as a potential craniate from the early Cambrian (Chen et al., 1999) but these interpretations are controversial (Shu et al., 1996). The earliest fossils attributed to the Vertebrata are enigmatic bits of bone from the late Cambrian described under the name *Anatolepis heintzi*. The vertebrate affinity of these fossils was challenged on various grounds, but recent analyses showed they contain dentine, a form of the calcium phosphate mineral apatite (the major mineral component of bone) that is found only in vertebrate skeletal tissues (Smith et al., 1996).

Homoiosteles and stylophorans, Paleozoic animals with a highly asymmetrical body form and a calcite skeleton resembling that of echinoderms, are another problematic extinct group. Fossils range in age from middle Cambrian to middle Devonian. The body can be divided into two distinct regions: a compact, asymmetrical region and a long segmented appendage. Interpretation of these fossils as “calcichordates,” a distinct assemblage of stem-group chordates (see Jefferies, 1986, 1997) is controversial. Most authors treat them as aberrant echinoderms, and the controversy over their affinity is based in part on interpretations of orientation and locomotion (see Parsley, 1997).

Vertebrate Classification

The classification of chordates has a long and complicated history. Traditionally, the vertebrates were divided into fishes, which occupied aquatic environments, and the tetrapods, which mainly occupied terrestrial habitats. At present, there are two major classification systems in use. The Linnaean classification system was first published by Linnaeus about 1758 and organizes major divisions of life into kingdoms (Plantae, Animalia, Fungi, etc.), with major body plans organized into phyla (singular: phylum). The basic ranks descend from phylum to class, order, family, genus, and species. This classification system is familiar to most teachers and students and remains the dominant classification taught to elementary and high school students in the United States (Figure 1). In the past several decades, a nonranked

- Kingdom Animalia
 - Phylum Chordata (chordates)
 - Subphylum Urochordata (tunicates)
 - Subphylum Cephalochordata (lancelets)
 - Subphylum Vertebrata (hagfish + vertebrates)
 - Class Myxini (hagfishes)
 - Class Cephalaspidomorphi (lampreys)
 - Class Chondrichthyes (chimaeras, sharks, skates, rays)
 - Class Osteichthyes (bony fishes)
 - Subclass Actinopterygii (teleosts, etc.) (many orders)
 - Subclass Sarcopterygii (lobe-finned fishes)
 - Order Crossopterygii (includes coelacanth)
 - Order Dipnoi (lungfishes)
 - Class Amphibia (amphibians)
 - Order Gymnophiona (caecilians)
 - Order Anura (frogs and toads)
 - Order Caudata (salamanders)
 - Class Reptilia (reptiles)
 - Order Testudines (turtles)
 - Order Rhynchocephalia (tuatara)
 - Order Lacertilia (lizards)
 - Order Serpentes (snakes)
 - Order Amphisbaenia (amphisbaenians)
 - Order Crocodylia (alligators and crocodiles)
 - Class Aves (birds)
 - (many orders)
 - Class Mammalia (mammals)
 - Order Monotremata (echidnas and platypus)
 - Order Marsupialia (marsupials)
 - (18 placental orders)

Figure 1 A traditional, Linnean classification of the major chordate groups. The major vertebrate groups are ranked into eight categories, all given the equivalent rank of class.

classification system was described by Hennig, a European entomologist. This classification system, termed “phylogenetic systematics” or “cladistics,” organizes taxa into nested sets of monophyletic groups based on common ancestry (a monophyletic group contains an ancestor and all of that ancestor’s descendants). A classification system based on natural groupings of taxa (based on ancestor–descendant relationships) is thus achieved. Phylogenetic systematics is rapidly becoming an important alternative classification system and is increasingly being utilized in biological sciences (including paleontology). Although we provide ancestry-based definitions for all the major chordate groups discussed below, we include three figures to illustrate the differences in classification systems now in use. Figure 1 illustrates a version of a Linnaean classification system, in which taxa are placed in equivalent ranks. Figures 2 and 3 are graphic representations of cladistic classifications, showing the hierarchical arrangement of nested taxa (Figure 2 shows the relationships of the major chordate groups, and Figure 3 shows the relationships of the major groups nested within the taxon Tetrapoda).

Definitions and Diagnoses of Major Chordate Groups

The major chordate groups discussed below are *defined* in terms of their ancestry; in other words, membership in a given taxon is dependent upon shared ancestry. Taxa are *diagnosed* by

Figure 2 A graphic representation of a cladistic classification of chordates. The major groups are arranged in a nested hierarchy, and taxon names are defined based on shared ancestry. The groups nested within Tetrapoda are depicted in **Figure 3**. See text for definitions and diagnoses.

a list of characteristics hypothesized to have first appeared in the common ancestor of the members of the group; this assemblage of characters can be used to identify a taxon (see Rowe, 1987, for further discussion).

Chordata

Chordata is defined as the most recent common ancestor of tunicates and cephalochordates, and all of that ancestor's descendants. Chordates share a common, generalized body plan and can be diagnosed by four features shared by members of all the major groups: a notochord, pharyngeal slits, a hollow dorsal nerve tube, and a postanal tail (an extension of the body posterior to the anus). The notochord is a stiff, flexible rod running dorsal to the coelom along the length of the body beneath the central nervous system. In many vertebrates, the notochord is almost completely replaced by blocks of bone forming vertebrae. Pharyngeal slits are lateral openings from the pharynx (an organ situated behind the mouth that constitutes part of the digestive tract). These features are found in all chordates at some point during their lifetime, but they are not retained as fully functional units throughout life in all chordates.

The tunicates (urochordates) are a group of basal chordates represented by approximately 3000 species. They are entirely marine. Some tunicates spend their entire life as pelagic

organisms, floating in the water column. One group of tunicates, the sea squirts, undergo a dramatic metamorphosis from a planktonic larval form to a sessile adult (attached to a substrate); a notochord is present in the tail of the larval stage but is resorbed in the adult during metamorphosis. The pharynx enlarges in the adult and expands to form a barrel-shaped branchial basket through which a constant flow of water passes as the animal filter-feeds.

Cephalochordata

Cephalochordata is defined as the most recent common ancestor of lancelets and Craniata, and all of that ancestor's descendants. Cephalochordates are diagnosed by the presence of segmented muscle blocks. The lancelets are marine organisms that live in shallow, tropical and temperate seas surrounding all the continental land masses except Antarctica. Two major groups are recognized and are classified under the names *Branchiostoma* (23 species) and *Epigonichthyes* (7 species; Poss and Boschung, 1996). Lancelets lack a well-differentiated head region. A rudimentary brain is present, but significant regions of the brain found in vertebrates appear to be absent. A recent volume addressing many aspects of lancelet biology (Gans *et al.*, 1996) provides an important foundation for future research on this group.

Figure 3 A graphic representation of a cladistic classification of tetrapods. The major groups are arranged in a nested hierarchy, and taxon names are defined based on shared ancestry. See text for definitions and diagnoses.

Craniata

Craniata is defined as the most recent common ancestor of hagfishes and Vertebrata, and all of that ancestor's descendants. Craniates are diagnosed by the presence of a differentiated head, with well-developed paired sense organs designed to act as distance receptors. There are 43 described species of hagfishes; all are marine organisms, and the group has a worldwide distribution. Hagfishes are scavengers, feeding on dead and moribund fishes, worms, mollusks, and crustaceans. They lack recognizable vertebral structures but have weakly developed, irregularly shaped plates that are positioned almost randomly along the nerve chord in the tail region. Their eyesight is poor, but they have well-developed senses of smell and touch. Reproductive biology is poorly understood; only a few embryos are known. Hagfishes were not known as fossils until 1991. The first reported fossil was found in Pennsylvanian age rocks in Illinois (Bardack, 1991). It differs from living forms in at least a few features (better developed eyes, different position of the gills, and some aspects of the feeding apparatus).

Vertebrata

Vertebrata is defined as the most recent common ancestor of lampreys and Gnathostomata, and all of that ancestor's

descendants. As noted above, Vertebrata is diagnosed by a suite of characters (see Table 1). In all vertebrates there is at least some development of vertebral elements. The basal members of Vertebrata, the lampreys, have only rudimentary development of these structures. Lamprey vertebral elements consist of tiny distinct cartilages, situated above the dorsal nerve cord. The homologies of these elements with vertebral units in other vertebrates are not known. Many adult lampreys are parasites on other fish, and sometimes act as scavengers. They have a circular mouth with a rasping tongue; the mouth is used like a suction cup to attach the lamprey to a fish, and the tongue is used to open a hole in the body cavity of the fish, providing access to the body fluids on which the lampreys feed. Some lampreys spend significant portions of their adult lives in marine habitats, but all lampreys return to freshwater to breed. There are approximately 32 living species of lampreys.

Many earlier classifications placed lampreys, hagfishes, and a diverse suite of extinct jawless fishes into the class Agnatha ("without jaws"). A great diversity of jawless marine vertebrate groups populated Ordovician, Silurian, and Devonian seas. One enigmatic group, the conodonts, were first discovered in 1856 and subsequently were found to be remarkably abundant in marine rocks dating from the late Cambrian through the Triassic. For over a century, conodonts were known only from abundant, tiny, phosphatic, toothlike fossils that showed

a remarkable diversity in form. These fossils were, and remain, important tools for establishing correlation and relative chronology of Paleozoic and early Mesozoic rocks. The systematic position of conodonts was debated for decades, and various authorities suggested affinities with many different animal groups. In 1983, a conodont fossil with soft-body preservation was reported for the first time (Briggs et al., 1983). Subsequent finds that preserve greater anatomical detail revealed several features that can be interpreted as a notochord, a dorsal nerve cord, myotomes, and a distinct head region with very large eyes. These features suggest that conodonts may well have been chordates, or possibly vertebrates, but the relationships of conodonts and other jawless fishes are still quite controversial (for reviews, see Benton, 1997; Zimmer, 2000).

Gnathostomata

Gnathostomata is defined as the most recent common ancestor of Chondrichthyes and Osteichthyes, and all of that ancestor's descendants. Gnathostomata is diagnosed by the presence of jaws, an enlarged forebrain, and a skeleton in the paired pectoral and pelvic appendages. The evolution of jaws provided new opportunities for vertebrates by opening the door to truly predatory habits, with new food-handling capabilities and a broader diversity in potential diet. Among living vertebrates the chondrichthyans constitute the basal members of Gnathostomata. There are approximately 850 species of living chondrichthyans, including the sharks, skates, rays, and chimaeras. The majority are marine, but a few species inhabit freshwater environments. There is no bony skeleton; the skeleton is predominantly cartilaginous, with only minor calcification occurring throughout. Males have special structures called claspers that help facilitate internal fertilization. The sharks first appear in the fossil record in the late Devonian, chimaeras appear in the Carboniferous, and rays appear in the Jurassic. The whale shark (*Rhincodon typus*) is the largest living fish, achieving lengths of up to 15 meters.

Osteichthyes

Osteichthyes is defined as the most recent common ancestor of Actinopterygii and Sarcopterygii, and all of that ancestor's descendants. Osteichthyes is diagnosed by the presence of lungs (see below) and by most of the bony skeleton being formed from cartilaginous precursors. Many bony fishes have an elongated sac, the gas bladder, situated dorsal to the digestive tract. Gas bladders can serve either a buoyancy control function (swim bladder) or a gas exchange function (respiratory gas bladder). In the latter condition, they are highly vascularized and serve as a supplementary reserve for oxygen to be used in respiration. Although gas bladders and lungs differ in their position relative to the digestive tract (lungs are ventral to the digestive tract) and lungs tend to be paired while gas bladders are single, their developmental origins and gross anatomical features are quite similar. These similarities provide some evidence that the two structures are homologous. Actinopterygii includes a remarkably diverse assemblage of fishes, including more than half of the living species of

known vertebrates; over 24,000 valid species are known (see Eschmeyer, 1998). The skeleton of actinopterygians is extensively ossified and the internal pectoral skeleton has broad bony plates that facilitate support of fin rays.

Sarcopterygii

Sarcopterygii is defined as the most recent common ancestor of Actinistia and Choanata, and all of that ancestor's descendants. Sarcopterygii is diagnosed by the presence of fleshy, lobed appendages, with differentiated proximal limb bones in the pectoral and pelvic fins, and by the presence of a ring of four or more bony plates in the eye (the sclerotic, or scleral, ring). Actinistia includes at least one, and possibly two, species of living coelacanths. These fishes first appear in the fossil record in the Devonian and make their last appearance in the fossil record near the end of the Cretaceous, approximately 70 million years ago. The discovery of an extant species of coelacanth off the coast of South Africa in 1938 was therefore quite surprising. Waters near the Comoro Islands (situated between the northern tip of Madagascar and the African mainland) yielded a second specimen in 1952, and subsequently approximately 200 additional specimens were recovered. An additional population of coelacanths was recently discovered in Indonesia (Erdmann et al., 1998; Forey, 1998). Analysis of the DNA of the Indonesian coelacanth suggests that it might belong to a new species, but this interpretation is controversial (Holden, 1999).

Choanata

Choanata is defined as the most recent common ancestor of Dipnoi and Tetrapoda, and all of that ancestor's descendants. Choanata is diagnosed by the presence of folded tooth enamel and choanae (internal nostrils that open directly into the palatal portion of the roof of the mouth). The lungfishes (Dipnoi) first appear in the fossil record in the Devonian and are represented by six living species. Their modern distribution is restricted to the southern continents of Africa, Australia, and South America. The Australian lungfish is the least derived of the three; it cannot live out of water but can survive in stagnant pools by coming to the surface to gulp air. The South American and African lungfishes can survive out of water for relatively long periods of time.

Tetrapoda

Tetrapoda is defined as the most recent common ancestor of Amphibia and Amniota, and all of that ancestor's descendants. Tetrapoda is diagnosed by the presence of differentiated fingers and toes and by a bony joint formed between the occipital condyles of the skull and the anterior vertebral elements.

Extant amphibians share three morphological characteristics: (1) loss of several skull bones found in extinct amphibian groups; (2) short or absent ribs; (3) pedicellate dentition (an upper tooth crown resting on a lower pedicel). The relationships among the three major extant amphibian groups are not well supported, but combined analyses of morphological and molecular data favor a sister taxon

relationship between Anura (frogs and toads) and Caudata (salamanders). Batrachia is defined as the most recent common ancestor of Anura and Caudata, and all of its descendants. In this arrangement, Batrachia and Gymnophiona (the caecilians) are sister taxa (**Figure 1**; see also Cannatella and Hillis, 1993).

There are approximately 165 species of living caecilians. All extant caecilians are limbless, and their distribution encompasses tropical and subtropical regions of Central and South America, Africa, India, and Southeast Asia. Most caecilians are fossorial, spending the majority of their life underground. One South American group (*Typhlonectes*) is secondarily aquatic. The otic capsules, exoccipital, basioccipital, and parasphenoid ossifications of the braincase are fused into a solid unit (the os basale). Caecilians possess a pair of sensory organs called tentacles that are unique among vertebrates. The tentacles are protrusible organs, usually situated between the external naris and the orbit, and probably function in chemoreception. Although the orbits of caecilians are often covered with skin (and sometimes bone), the eyes are photoreceptive in most species that have been examined. In some caecilians, the eye is closely associated with the tentacle and in at least one species, they eye is protruded from the skull during protrusion of the tentacle (Nussbaum, 1992). The derived groups of caecilians fuse many elements of the skull and lack a tail. The fossil record of caecilians is notably poor but extends back at least as far as the Cretaceous. The Jurassic *Eocaecilia* shares many characteristics with extant caecilians (including the reported presence of a tentacular foramen) but retains limbs and other anatomical features not seen in extant forms (Jenkins and Walsh, 1993).

There are approximately 415 described species of extant salamanders, the majority of which are found in the Northern Hemisphere. A significant radiation of tropical South American salamanders extends as far south as southern Brazil and Bolivia. Caudates share a number of morphological features of the skeleton, including the loss of the quadratojugal ossification and the presence of intravertebral spinal foramina in the atlas vertebra. Most salamanders also have a reduced number of bones in the pectoral girdle relative to extinct amphibian groups and frogs (caecilians lack a pectoral girdle), and they have an anteriorly projecting process on the atlas (the first vertebra), the tuberculum interglenoideum, which forms accessory articulations between the skull and the vertebral column. Members of one large assemblage of caudates (the Plethodontidae) lack lungs, and this condition is also found in one gymnophionan. The early history of salamanders is poorly known, but fossils belonging to Caudata (as defined above) are known from the Mesozoic. Stem-group salamanders (outside of Caudata as defined above, but on the evolutionary stem leading to modern salamanders) are reported from the Jurassic. A recent review of Mesozoic taxa was provided by Evans and Milner (1996).

There are more than 4100 described species of extant anurans, distributed on all the major continental land-masses except Antarctica. Skeletal features shared by frogs include the fusion of forearm bones (radius and ulna), fusion of the lower leg bones (tibia and fibula), elongation of the ankle bones, reduced number of trunk vertebrae (10 or fewer among extant frogs), and presence of a urostyle (a rodlike, posterior bony

extension of the vertebral column). Many of these skeletal features are associated with jumping ability and evolved as early as the early Jurassic (Shubin and Jenkins, 1995). The fossil record of the group is extensive (see recent review by Sanchiz, 1998) and at least two stem-group frogs are now known from the early Triassic (Evans and Borsuk-Bialynicka, 1998).

Many amphibians have a larval stage followed by metamorphosis into the adult form. Metamorphosis was defined by Duellman and Trueb (1986, p. 173) as “a series of abrupt postembryonic changes involving structural, physiological, biochemical, and behavioral transformations.” The transformations that take place in frogs are the most dramatic of any within the Tetrapoda. The majority of frog species have a larval stage in the life cycle (following hatching from an egg and preceding development of the mature adult body form) known as a tadpole. The tadpole has a more or less oval-shaped body with a tail; there is no distinct head region, but the mouth includes a beak and a number of rows of chitinous toothlike structures. During metamorphosis many morphological and physiological changes take place that completely transform the animal’s appearance and the way it interacts with its environment (e.g., the tail is resorbed, limbs grow, the axial and appendicular skeleton is dramatically transformed, the digestive tract shortens, gills disappear, and respiration function is transferred to lungs). Many frogs show variants of direct development.

Amniota

Amniota is defined as the most recent common ancestor of Reptilia and Mammalia, and all of that ancestor’s descendants. Amniota is diagnosed by a suite of characters, including presence of an amniote egg (see below), caniniform teeth, two or more vertebrae in contact with the pelvic girdle, internal fertilization, and keratin (a protein that acts as the building block for scales, nails, hooves, hair, and feathers). The amniote egg includes a series of extraembryonic membranes that surround the developing embryo and provide all the nutritional, waste disposal, and gas exchange requirements during development. In reptiles (including birds) and the Monotremata (basal mammals), the embryo and extraembryonic membranes are encapsulated in an egg with either a leathery exterior or a hard shell. Because this is a self-contained fluid-filled system, eggs can be laid away from water. Although fishes, amphibians, and most reptiles are often referred to as “cold-blooded,” many species in these groups manage to maintain elevated body temperature at a constant level. This is achieved by shuttling between heat sources and heat sinks (ectothermy). However, birds and mammals generally maintain a constant temperature by changing the basal metabolic rate (endothermy). There is substantial evidence suggesting that some of the fossil reptiles did maintain body temperatures above the level of the environment. There has been much argument about the question of whether the mechanism by which this was achieved was ectothermy or endothermy. The earliest known members of the Amniota appear in the fossil record during the Pennsylvanian period.

Reptilia

Reptilia is defined as the most recent common ancestor of Chelonia and Sauria, and all of that ancestor's descendants. Reptilia is diagnosed by several features of the skull, including the presence of suborbital fenestrae (paired openings in the skull that are situated ventral to the orbital region).

There are approximately 260 species of extant Chelonia (turtles). They are found on all continental land-masses except Antarctica and also occupy all of the world's tropical and temperate oceans and seas. All turtles lack marginal teeth, but the earliest known stem-group turtles (*Proganochelys*) from the Triassic have a few small teeth on the palatal portion of the skull; all extant chelonians lack palatal teeth. The palate is firmly attached to the braincase. The presence of a hard, bony shell is one of the most distinguishing features of turtles. The upper portion of the shell (the carapace) is formed in part from the vertebral column and ribs. During development these elements fuse with dermal ossifications to form a generally continuous, hard bony shell. The generally flat, ventral plate (the plastron) of the shell is formed anteriorly by dermal bones and skeletal elements that are probably homologous with elements of the pectoral girdle in other vertebrates. The bony shell of most turtles is covered by a series of keratinous scutes; in some forms, these scutes are lacking and a leathery skin covers the carapace and plastron. Turtles are unique among vertebrates in having the pectoral girdle enclosed by the rib cage. Turtles first appear in the fossil record during the Triassic.

Sauria

Sauria is the most recent common ancestor of Lepidosauria and Archosauria, and all of that ancestor's descendants. Sauria is diagnosed by the presence of a specialized ankle joint, long and generally slender hind limbs, and relatively larger leg muscles.

Lepidosauria can be defined as the most recent common ancestor of Squamata and the extant rhynchocephalian (*Sphenodon*; see below), and all of that ancestor's descendants. Lepidosauria is diagnosed by various features of the skull and the presence of a transverse cloacal slit, a distally notched tongue, and a modified middorsal scale row. Rhynchocephalians were a very diverse and widespread group of lepidosaurs during the Mesozoic era, but by approximately 60 million years ago, they were extinct everywhere except in New Zealand. The last surviving rhynchocephalians are restricted to a few islands in New Zealand. These relict populations are classified in the genus *Sphenodon*, and two species are currently recognized.

Squamata includes all the lizards and snakes as well as the fossorial amphisbaenians. A number of anatomical features are shared by these three groups, including aspects of the skull, postcranial skeleton, musculature, and tongue. All squamates have paired, evertible hemipenes. Many squamate species lack, or have reduced, limbs and girdles.

There are approximately 4150 species of extant lizards, widely distributed on all the continents except Antarctica. A number of extinct groups were fully marine, but today only one species utilizes a marine habitat (the marine iguana of the

Galapagos Islands feeds on marine algae). Many groups of lizards have lost or reduced limbs. The two North American species of *Heloderma* are venomous. Lizards first appear in the fossil record in the Jurassic.

Both morphological and molecular data indicate that snakes evolved from within lizards, but their precise phylogenetic position among other squamates is unresolved. There are approximately 2700 species of extant snakes, with a distribution encompassing tropical oceans and seas and all continents except Antarctica. Several species spend most or all of their lives in open ocean habitats. Most snakes are limbless, but some basal members retain vestigial pelvic girdle and limb elements. A few poorly known Mesozoic snakes had well-developed limbs. All snakes are carnivorous, and several lineages of advanced snakes evolved potent venom that lets them subdue prey. Most snake species have an extremely modified and flexible skull structure that permits them to eat animals much more bulky than themselves and to ingest prey that is of a greater diameter than their own head. Snakes first appear in the fossil record during the Cretaceous, but their fossil record as a whole is relatively poor and consists predominantly of isolated vertebrae.

Amphisbaenia is a small group of squamates with approximately 160 extant species. They are found in Africa, the Iberian Peninsula, the Middle East, Mexico, from Panama to Argentina in South America, and Georgia and Florida in the southeastern United States. As a result of their subterranean habits and the fact that almost one-third of the described species are known from only one specimen, many aspects of their biology and systematics are not well understood. Three species of *Bipes* retain anterior limbs, but all other species are limbless. The compact and well-ossified skull is the primary burrowing tool and is covered with relatively large scales. The scales of the skin are usually rectangular and are arranged in rings that encircle the body and allow rectilinear locomotion. Amphisbaenians first appear in the fossil record in the late Paleocene of North America.

Archosauria is defined as the most recent common ancestor of Crocodylia and Aves, and all of that ancestor's descendants. Archosaurs are diagnosed by a number of anatomical features and also by behavioral characteristics such as nest building and parental care of young. The two extant groups of archosaurs represent only a tiny fraction of the past diversity of this group, which includes the Mesozoic flying reptiles (pterosaurs), all the dinosaurs, and many extinct crocodylians.

There are 22 extant species of Crocodylia (alligators, crocodiles, and caimans), most of which are found in the Tropics. Two species of alligators extend into temperate regions in North America and China. The earliest known crocodylians were terrestrial, but all living species are found in aquatic habitats. Some extant species are found in nearshore marine habitats, but none are fully marine. Crocodylians have a complete secondary palate that forms the roof of the mouth (similar to the configuration seen in mammals). Stem-group crocodylians are known from the late Triassic, but the earliest true crocodylians are found in early Jurassic rocks.

Aves is defined as the most recent common ancestor of all extant birds, and all of that ancestor's descendants. There are approximately 9700 species of extant birds. In traditional

classifications, Aves was considered to be a separate class of vertebrates, equivalent in rank to the Amphibia, Mammalia, and Reptilia. Cladistic classifications recognize birds as a distinctive group of vertebrates, but one that is nested within Reptilia, specifically within the Dinosauria. Although not accepted by all ornithologists, there is strong morphological support for this hypothesis. Birds and dinosaurs share such morphological features as an in-turned femoral head, opposable thumb, and a perforate acetabulum. An additional suite of characters indicate that birds are nested within theropod dinosaurs. Aves (as defined above) is diagnosed by the loss of teeth, the presence of a pneumatic foramen in the humerus (upper arm bone), and fusion of uncinat processes with the ribs. Most extant bird lineages appear in the fossil record at least by the early Cenozoic, and several are reported from the Cretaceous.

Mammalia

Mammalia is defined as the most recent common ancestor of Monotremata and Theria (marsupials plus placentals), and all of that ancestor's descendants. Mammalia is diagnosed by a large number of anatomical and physiological features, including the presence of mammary glands and a unique jaw joint. Mammary glands in females produce milk to nourish the rapidly growing young during postnatal development. In most vertebrates the jaw joint is formed between the quadrate bone of the skull and the articular bone of the lower jaw, but in mammals, the jaw joint is formed between the dentary bone (the only bone in the lower jaw of mammals) and the squamosal bone of the skull. Bones homologous with the quadrate and articular are still present in mammals, but their positional relationship and function has been transformed. The incus and malleus in the middle ear of mammals are homologous with the quadrate and articular (respectively) in other vertebrates. The 4810 species of extant mammals can be found on all continents and major bodies of water on Earth.

Monotremata is represented by three living species (duck-billed platypus and two species of echidna) that are found only in Australia and New Guinea, but the fossil record of this group extends back to the Cretaceous and reveals that monotremes were once found in South America. The monotremes are the only mammals that lay eggs. The marsupials are found today only in Australia and surrounding islands, North America, and South America. Their earliest appearance in the fossil record is in the Cretaceous of North and South America, and fossils are known from all continental landmasses. Marsupials differ from other mammals in a number of physiological and anatomical features, especially those related to reproduction. The gestation period in marsupials is very short compared with that of other mammals and the young are born in a nearly embryonic state. After birth, development takes place in a pouch (or sometimes under a fold of skin) on the mother's abdomen. The Placentalia includes a diverse assemblage of mammals that include many of the most familiar mammals and the only mammals to adopt a completely or predominantly marine lifestyle (whales, dolphins, porpoises, seals, sea lions, walruses) and to achieve powered flight (bats).

Human beings are members of a placental mammal group, the Primates.
